TEXTBOOK OF CRITICAL CARE

7th Edition

Textbook of Critical Care, Seventh Edition

Table of Contents

| | | |
|---|--|---|
| <u>Front Matter</u> | 21. <u>Thrombocytopenia</u> | <u>Weakness</u> |
| <u>Copyright</u> | 22. <u>Coagulopathy in the ICU</u> | 47. <u>Advanced Bedside Neuromonitoring</u> |
| <u>Dedications</u> | 23. <u>Jaundice</u> | 48. <u>Coma</u> |
| <u>In Memoriam</u> | 24. <u>Gastrointestinal Bleeding</u> | 49. <u>Use of Brain Injury Biomarkers in Critical Care Settings</u> |
| <u>Contributors</u> | 25. <u>Ascites</u> | 50. <u>Cardiopulmonary Cerebral Resuscitation</u> |
| <u>Preface</u> | 26. <u>Acute Abdominal Pain</u> | 51. <u>Delirium</u> |
| 1. <u>Sudden Deterioration in Neurologic Status</u> | 27. <u>Ileus</u> | 52. <u>Management of Acute Ischemic Stroke</u> |
| 2. <u>Agitation and Delirium</u> | 28. <u>Diarrhea</u> | 53. <u>Nontraumatic Intracerebral and Subarachnoid Hemorrhage</u> |
| 3. <u>Management of Acute Pain in the Intensive Care Unit</u> | 29. <u>Rash and Fever</u> | 54. <u>Seizures in the Critically Ill</u> |
| 4. <u>Fever</u> | 30. <u>Chest Pain</u> | 55. <u>Neuromuscular Disorders in the Critically Ill</u> |
| 5. <u>Very High Systemic Arterial Blood Pressure</u> | 31. <u>Biochemical or Electrocardiographic Evidence of Acute Myocardial Injury</u> | 56. <u>Traumatic Brain Injury</u> |
| 6. <u>Low Systemic Arterial Blood Pressure</u> | 32. <u>Point-of-Care Ultrasound</u> | 57. <u>Spinal Cord Injury</u> |
| 7. <u>Tachycardia and Bradycardia</u> | 33. <u>Echocardiography</u> | 58. <u>Neuroimaging</u> |
| 8. <u>Arterial Hypoxemia</u> | 34. <u>Cardiovascular Monitoring</u> | 59. <u>Intensive Care After Neurosurgery</u> |
| 9. <u>Acute Respiratory Failure</u> | 35. <u>Bedside Monitoring of Pulmonary Function</u> | 60. <u>Key Issues in Pediatric Neurointensive Care</u> |
| 10. <u>Pulmonary Edema</u> | 36. <u>Arterial Blood Gas Interpretation</u> | 61. <u>Patient-Ventilator Interaction</u> |
| 11. <u>Polyuria</u> | 37. <u>Tracheal Intubation</u> | 62. <u>Noninvasive Positive-Pressure Ventilation</u> |
| 12. <u>Oliguria</u> | 38. <u>Tracheostomy</u> | 63. <u>Weaning from Mechanical Ventilation</u> |
| 13. <u>Hypernatremia and Hyponatremia</u> | 39. <u>Mechanical Ventilation</u> | 64. <u>Adjunctive Respiratory Therapy</u> |
| 14. <u>Hyperkalemia and Hypokalemia</u> | 40. <u>Renal Replacement Therapy</u> | 65. <u>Hyperbaric Oxygen in Critical Care</u> |
| 15. <u>Hyperphosphatemia and Hypophosphatemia</u> | 41. <u>Targeted Temperature Management and Therapeutic Hypothermia</u> | 66. <u>Imaging of the Chest</u> |
| 16. <u>Hypomagnesemia</u> | 42. <u>Extracorporeal Membrane Oxygenation (Venovenous and Venoarterial ECMO)</u> | 67. <u>Acute Respiratory Distress Syndrome</u> |
| 17. <u>Hypocalcemia and Hypercalcemia</u> | 43. <u>Nutritional Support in Adults</u> | 68. <u>Aspiration Pneumonitis and Pneumonia</u> |
| 18. <u>Hypoglycemia</u> | 44. <u>Nutritional Support in Children</u> | |
| 19. <u>Hyperglycemia</u> | 45. <u>Early Ambulation in the ICU</u> | |
| 20. <u>Anemia</u> | 46. <u>Role of Early Mobilization in the Prevention of ICU-Acquired</u> | |

| | | |
|---|---|---|
| 69. <u>Severe Asthma Exacerbation</u> | <u>Cholecystitis</u> | <u>System Failure in Children</u> |
| 70. <u>Chronic Obstructive Pulmonary Disease</u> | 98. <u>Acute Pancreatitis</u> | 123. <u>Infections of the Urogenital Tract</u> |
| 71. <u>Pulmonary Embolism</u> | 99. <u>Peritonitis and Intraabdominal Infection</u> | 124. <u>Central Nervous System Infections</u> |
| 72. <u>Pulmonary Hypertension</u> | 100. <u>Ileus and Mechanical Bowel Obstruction</u> | 125. <u>Infections of Skin, Muscle, and Soft Tissue</u> |
| 73. <u>Pneumothorax</u> | 101. <u>Toxic Megacolon and Ogilvie's Syndrome</u> | 126. <u>Head and Neck Infections</u> |
| 74. <u>Community-Acquired Pneumonia</u> | 102. <u>Clinical Assessment of Renal Function</u> | 127. <u>Infections in the Immunocompromised Patient</u> |
| 75. <u>Nosocomial Pneumonia</u> | 103. <u>Biomarkers of Acute Kidney Injury</u> | 128. <u>Infectious Endocarditis</u> |
| 76. <u>Drowning</u> | 104. <u>Metabolic Acidosis and Alkalosis</u> | 129. <u>Fungal Infections</u> |
| 77. <u>Acute Parenchymal Disease in Pediatric Patients</u> | 105. <u>Water Metabolism</u> | 130. <u>Influenza</u> |
| 78. <u>Acute Coronary Syndromes : Therapy</u> | 106. <u>Disorders of Calcium and Magnesium Metabolism</u> | 131. <u>Human Immunodeficiency Virus Infection</u> |
| 79. <u>Supraventricular Arrhythmias</u> | 107. <u>Fluid and Volume Therapy in the ICU</u> | 132. <u>Tuberculosis</u> |
| 80. <u>Ventricular Arrhythmias</u> | 108. <u>Fluids and Electrolytes in Pediatrics</u> | 133. <u>Malaria and Other Tropical Infections in the Intensive Care Unit</u> |
| 81. <u>Conduction Disturbances and Cardiac Pacemakers</u> | 109. <u>Acute Kidney Injury</u> | 134. <u>Acute Viral Syndromes</u> |
| 82. <u>Myocarditis and Acute Myopathies</u> | 110. <u>Urinary Tract Obstruction</u> | 135. <u>Clostridium difficile Infection</u> |
| 83. <u>Acquired and Congenital Heart Disease in Children</u> | 111. <u>Contrast-Induced Acute Kidney Injury</u> | 136. <u>Anemia and RBC Transfusion</u> |
| 84. <u>Pericardial Diseases</u> | 112. <u>Glomerulonephritis</u> | 137. <u>Blood Component Therapies</u> |
| 85. <u>Emergency Heart Valve Disorders</u> | 113. <u>Interstitial Nephritis</u> | 138. <u>Venous Thromboembolism in Medical-Surgical Critically Ill Patients</u> |
| 86. <u>Infectious Endocarditis</u> | 114. <u>Antimicrobial Stewardship</u> | 139. <u>Monitoring of Coagulation Status</u> |
| 87. <u>Hypertensive Crisis : Emergency and Urgency</u> | 115. <u>Prevention and Control of Nosocomial Pneumonia</u> | 140. <u>Anticoagulation in the Intensive Care Unit</u> |
| 88. <u>Pathophysiology and Classification of Shock States</u> | 116. <u>Antimicrobial Agents with Primary Activity Against Gram-Negative Bacteria</u> | 141. <u>Critical Care of the Hematopoietic Stem Cell Transplant Recipient</u> |
| 89. <u>Resuscitation from Circulatory Shock</u> | 117. <u>Antimicrobial Agents with Primary Activity Against Gram-Positive Bacteria</u> | 142. <u>Cardiovascular and Endocrinologic Changes Associated with Pregnancy</u> |
| 90. <u>Inotropic Therapy</u> | 118. <u>Antimicrobial Agents Active Against Anaerobic Bacteria</u> | 143. <u>Hypertensive Disorders in Pregnancy</u> |
| 91. <u>Mechanical Support in Cardiogenic Shock</u> | 119. <u>Selective Decontamination of the Digestive Tract</u> | 144. <u>Acute Pulmonary Complications During Pregnancy</u> |
| 92. <u>Portal Hypertension : Critical Care Considerations</u> | 120. <u>Vascular Catheter-Related Infections</u> | 145. <u>Postpartum Hemorrhage</u> |

TEXTBOOK OF CRITICAL CARE

7TH EDITION

JEAN-LOUIS VINCENT, MD, PhD

Professor of Intensive Care Medicine
Université Libre de Bruxelles
Department of Intensive Care
Erasme University Hospital
Brussels, Belgium

EDWARD ABRAHAM, MD

Professor and Dean
Wake Forest School of Medicine
Winston-Salem, North Carolina

FREDERICK A. MOORE, MD, MCCM

Professor of Surgery
Head, Acute Care Surgery
Department of Surgery
University of Florida College of Medicine
Gainesville, Florida

PATRICK M. KOCHANEK, MD, MCCM

Ake N. Grenvik Professor in Critical Care Medicine
Professor and Vice Chairman
Department of Critical Care Medicine
Professor of Anesthesiology, Pediatrics, Bioengineering,
and Clinical and Translational Science
University of Pittsburgh School of Medicine
Director, Safar Center for Resuscitation Research
Pittsburgh, Pennsylvania

MITCHELL P. FINK, MD†

Professor of Surgery and Anesthesiology
Vice Chair for Critical Care
Department of Surgery
David Geffen School of Medicine at UCLA
Los Angeles, California

†Deceased.

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

PREFACE

We are pleased to bring you the Seventh Edition of *Textbook of Critical Care*. We've listened to our readers and have retained the acclaimed features that have made this book one of the top sellers in critical care, while also making changes to the organization and content of the book to best reflect the changes in the critical care specialty since the last edition.

Our tables, boxes, algorithms, diagnostic images, and key points, which provide clear and accessible information for quick reference, will continue to be featured prominently throughout the book. The Seventh Edition contains a wealth of new information, including an entirely new section on Common Approaches for Organ Support, Diagnosis, and Monitoring. In addition, we have added new chapters on Extracorporeal Membrane Oxygenation, Biomarkers of Acute Kidney Injury, Antimicrobial Stewardship, Targeted Temperature Management and Therapeutic Hypothermia, Telemedicine in Intensive Care, and many more. Given the increased use of bedside ultrasonography, a new chapter addressing best practices with this now ubiquitous tool has been added. All chapters throughout the book have been revised to reflect new knowledge in the field and, thus, changes in the practice of critical care medicine.

Textbook of Critical Care has evolved with critical care practice over the years and is now known as the reference that successfully bridges

the gap between medical and surgical intensive care practice. Unlike many critical care references, *Textbook of Critical Care* includes pediatric topics, providing a comprehensive resource for our readers who see a broad range of patients. We continue to focus on the multidisciplinary approach to the care of critically ill patients and include contributors trained in anesthesia, surgery, pulmonary medicine, and pediatrics.

The companion online book is more interactive than ever, with 29 procedural videos and 24 e-only procedural chapters, a powerful search engine, hyperlinked references, and downloadable images. The website is mobile optimized for your convenience on all portable devices. Access to the online content is included with your book purchase, so please activate your e-book to take advantage of the full scope of information available to you.

Jean-Louis Vincent, MD, PhD
Edward Abraham, MD
Frederick A. Moore, MD, MCCM
Patrick M. Kochanek, MD, MCCM
Mitchell P. Fink, MD

CONTRIBUTORS

Basem Abdelmalak, MD

Professor of Anesthesiology
Director of Anesthesia for Bronchoscopic Surgery
Departments of General Anesthesiology and Outcomes Research
Anesthesiology Institute
Cleveland Clinic
Cleveland, Ohio

Yasir Abu-Omar, MB ChB, DPhil, FRCS

Consultant Cardiothoracic and Transplant Surgeon
Papworth Hospital
Cambridge, Great Britain

Felice Achilli, MD

Chief of Cardiology
Cardiothoracic Department
San Gerardo University Hospital
Monza, Italy

Hernán Aguirre-Bermeo, MD

Intensive Care Department
Hospital Sant Pau
Barcelona, Spain

Ayub Akbari, MD, MSc

Associate Professor
Department of Medicine
University of Ottawa
Senior Clinical Investigator
Clinical Epidemiology Program
Ottawa Hospital Research Institute
Ottawa, Ontario, Canada

Louis H. Alarcon, MD, FACS, FCCM

Associate Professor of Surgery and Critical Care Medicine
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

F. Luke Aldo, DO

Department of Anesthesiology
Hartford Hospital
Hartford, Connecticut

Ali Al-Khafaji, MD, MPH, FACP, FCCP

Associate Professor
Department of Critical Care Medicine
Director
Transplant Intensive Care Unit
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Roland Amathieu, MD, PhD

Associate Professor
Critical Care Medicine and Anesthesiology
Henri Mondor Hospital - AP-HP
Associate Professor
UPEC - School of Medicine
Créteil, France

John Leo Anderson-Dam, MD

Assistant Clinical Professor
Department of Anesthesiology and Perioperative Medicine
University of California Los Angeles
Los Angeles, California

Rajesh K. Aneja, MD

Associate Professor
Department of Pediatrics and Critical Care Medicine
University of Pittsburgh School of Medicine
Medical Director
Pediatric Intensive Care Unit
Children's Hospital of Pittsburgh of UPMC
Pittsburgh, Pennsylvania

Massimo Antonelli, MD

Professor of Intensive Care and Anesthesiology
Department of Anesthesiology and Intensive Care
Agostino Gemelli University Hospital
Rome, Italy

Zarah D. Antongiorgi, MD

Assistant Clinical Professor
Department of Anesthesiology and Perioperative Medicine
Division of Critical Care
David Geffen School of Medicine at UCLA
Los Angeles, California

Anastasia Antoniadou, MD, PhD

Associate Professor of Internal Medicine and Infectious Diseases
University General Hospital ATTIKON
National and Kapodistrian University of Athens Medical School
Athens, Greece

Anupam Anupam, MBBS

Attending Physician
Department of Medicine
Advocate Illinois Masonic Medical Center
Chicago, Illinois

Lorenzo Appendini, ASLCN

Presidio Ospedaliero di Saluzzo
Saluzzo (Cuneo), Italy

Andrew C. Argent, MBBCh, MMed(Paediatrics), MD (Paediatrics), DCH(SA), FCPaeds(SA)

Professor
School of Child and Adolescent Health
University of Cape Town
Medical Director
Paediatric Intensive Care
Red Cross War Memorial Children's Hospital
Cape Town, South Africa

John H. Arnold, MD

Professor of Anaesthesia (Pediatrics)
Harvard Medical School
Senior Associate
Department of Anesthesia and Critical Care
Medical Director
Respiratory Care/ECMO
Children's Hospital
Boston, Massachusetts

Stephen Ashwal, MD

Distinguished Professor of Pediatrics and Neurology
Chief
Division of Pediatric Neurology
Department of Pediatrics
Loma Linda University School of Medicine
Loma Linda, California

Mark E. Astiz, MD

Professor of Medicine
Hofstra Northwell School of Medicine
Chairman
Department of Medicine
Lenox Hill Hospital
New York, New York

Arnold S. Baas, MD, FACC, FACP

Associate Clinical Professor of Medicine
University of California Los Angeles
David Geffen School of Medicine at UCLA
Los Angeles, California

Marie R. Baldisseri, MD, MPH, FCCM

Professor of Critical Care Medicine
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Zsolt J. Balogh, MD, PhD, FRACS, FACS

Professor of Traumatology
Department of Traumatology
John Hunter Hospital and University of Newcastle
Newcastle, New South Wales, Australia

Arna Banerjee MD, FCCM

Associate Professor of Anesthesiology/Critical Care
Associate Professor of Surgery
Medical Education and Administration
Assistant Dean for Simulation in Medical Education
Vanderbilt University Medical Center
Nashville, Tennessee

Shweta Bansal, MBBS, MD, FASN

Professor of Medicine
Division of Nephrology
University of Texas Health Sciences Center at San Antonio
San Antonio, Texas

Kaysie Banton, MD

Assistant Professor of Surgery
University of Minnesota
Minneapolis, Minnesota

Philip S. Barie, MD, MBA, FIDSA, FACS, FCCM

Professor of Surgery and Public Health
Weill Cornell Medicine of Cornell University
New York, New York

Igor Barjaktarevic, MD, MSc

Assistant Professor of Medicine
Division of Pulmonary and Critical Care
David Geffen School of Medicine at UCLA
Los Angeles, California

Barbara L. Bass, MD

John F., Jr., and Carolyn Bookout Presidential Distinguished Chair
Department of Surgery
Professor of Surgery
Houston Methodist Hospital
Houston, Texas
Professor of Surgery
Weill Cornell Medicine of Cornell University
New York, New York

Gianluigi Li Bassi, MD, PhD

Department of Pulmonary and Critical Care Medicine
Hospital Clinic Calle Villarreal
Barcelona, Spain

Sarice L. Bassin, MD

Medical Director, Stroke Program
PeaceHealth Southwest Medical Center
Vancouver, Washington

Julie A. Bastarache, MD

Assistant Professor of Medicine
Division of Allergy, Pulmonary, and Critical Care Medicine
Vanderbilt University School of Medicine
Nashville, Tennessee

Daniel G. Bausch, MD, MPH&TM

Professor
 Department of Tropical Medicine
 Tulane School of Public Health and Tropical Medicine
 Clinical Associate Professor
 Department of Medicine
 Section of Adult Infectious Diseases
 Tulane Medical Center
 New Orleans, Louisiana

Hülya Bayır, MD

Professor of Critical Care Medicine
 University of Pittsburgh School of Medicine
 Director of Research, Pediatric Critical Care Medicine
 Associate Director, Center for Free Radical and Antioxidant Health
 University of Pittsburgh Medical Center
 Pittsburgh, Pennsylvania

Yanick Beaulieu, MD, FCRPC

Cardiologue-Échocardiographe/Intensiviste
 Hôpital du Sacré-Coeur de Montréal
 Professeur Adjoint de Clinique
 Université de Montréal
 Montréal, Québec, Canada

Thomas M. Beaver, MD, MPH

Professor of Surgery
 Chief
 Division of Thoracic and Cardiovascular Surgery
 University of Florida College of Medicine
 Gainesville, Florida

Gregory Beilman, MD

Deputy Chair
 Department of Surgery
 Director of System Critical Care Program
 University of Minnesota Health System
 Minneapolis, Minnesota

Michael J. Bell, MD

Associate Professor
 Departments of Critical Care Medicine, Neurological Surgery,
 and Pediatrics
 University of Pittsburgh School of Medicine
 Associate Director
 Safar Center for Resuscitation Research
 Pittsburgh, Pennsylvania

Giuseppe Bello, MD

Department of Anesthesia and Intensive Care
 Agostino Gemelli University Hospital
 Università Cattolica del Sacro Cuore
 Rome, Italy

Peyman Benharash, MD

Assistant Professor of Bioengineering
 Division of Cardiothoracic Surgery
 University of California Los Angeles
 David Geffen School of Medicine at UCLA
 Los Angeles, California

Adriana Bermeo-Ovalle, MD

Assistant Professor
 Department of Neurological Sciences
 Rush University Medical Center
 Chicago, Illinois

Gordon R. Bernard, BS, MD

Professor of Medicine
 Department of Medicine
 Vanderbilt University School of Medicine
 Nashville, Tennessee

Cherisse D. Berry, MD

Clinical Instructor
 Department of Surgery
 University of Maryland School of Medicine
 Baltimore, Maryland

Beth Y. Besecker, MD

Assistant Professor of Medicine
 Division of Pulmonary, Allergy, Critical Care, and Sleep Medicine
 The Ohio State University Wexner Medical Center
 Columbus, Ohio

Joost Bierens, MD

Professor of Emergency Medicine
 VU University Medical Centre
 Amsterdam, The Netherlands

Walter L. Biffl, MD

Associate Director of Surgery
 Denver Health Medical Center
 Denver, Colorado
 Professor of Surgery
 University of Colorado
 Aurora, Colorado

Thomas P. Bleck, MD, MCCM

Professor
 Departments of Neurological Sciences, Neurosurgery, Internal
 Medicine, and Anesthesiology
 Rush Medical College
 Director
 Clinical Neurophysiology
 Rush University Medical Center
 Chicago, Illinois

Thomas A. Bledsoe, MD

Clinical Associate Professor of Medicine
 Division of Critical Care
 Pulmonary and Sleep Medicine
 The Warren Alpert Medical School at Brown University
 Vice-Chair
 Ethics Committee
 Rhode Island Hospital
 Providence, Rhode Island

Karen C. Bloch, MD, MPH, FIDSA, FACP

Associate Professor
Departments of Medicine (Infectious Diseases) and Health Policy
Vanderbilt University Medical Center
Nashville, Tennessee

Desmond Bohn, MD

Professor of Pediatrics and Anesthesia
University of Toronto
Toronto, Ontario

David Boldt, MD, MS

Assistant Clinical Professor, Critical Care Medicine
Chief, Trauma Anesthesiology
University of California Los Angeles
David Geffen School of Medicine at UCLA
Los Angeles, California

Geoffrey J. Bond, MD

Assistant Professor in Transplant Surgery
Thomas E. Starzl Transplantation Institute
University of Pittsburgh School of Medicine
Transplant Director
Pediatric Intestinal Care Center
Children's Hospital of Pittsburgh of UPMC
Pittsburgh, Pennsylvania

Michael J. Bradshaw, MD

Resident Physician
Department of Neurology
Vanderbilt University School of Medicine
Nashville, Tennessee

Luca Brazzi, MD

Associate Professor
Department of Anesthesia and Intensive Care Medicine
S. Giovanni Battista Molinette Hospital
University of Turin
Turin, Italy

Serge Brimioulle, MD, PhD

Professor of Intensive Care
Department of Intensive Care
Erasme Hospital
Université Libre de Bruxelles
Brussels, Belgium

Itzhak Brook, MD

Professor of Pediatrics
Georgetown University School of Medicine
Washington, DC

Richard C. Brundage, PharmD, PhD, FISoP

Distinguished University Teaching Professor
Professor of Experimental and Clinical Pharmacology
University of Minnesota College of Pharmacy
Minneapolis, Minnesota

Sara T. Burgardt, MD, PharmD

Subspecialty Fellow
Adult Nephrology
Department of Medicine
Division of Nephrology
University of North Carolina
Chapel Hill, North Carolina

Sherilyn Gordon Burroughs, MD

Associate Professor of Surgery
Weill Cornell Medicine of Cornell University
Houston Methodist Hospital
Sherrie and Alan Conover Center for Liver Disease and
Transplantation
Houston, Texas

Clifton W. Callaway, MD, PhD

Professor of Emergency Medicine
Executive Vice-Chairman of Emergency Medicine
Ronald D. Stewart Endowed Chair of Emergency Medicine Research
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Peter M.A. Calverley, MB ChB, MD

Professor of Respiratory Medicine
Respiratory Research Department
University of Liverpool
Liverpool, Great Britain

**John Camm, QHP, MD, BsC, FMedSci, FRCP, FRCP(E),
FRCP(G), FACC, FESC, FAHA, FHRS, CStJ**

Professor of Clinical Cardiology
Clinical Academic Group
Cardiovascular and Cell Sciences Research Institute
St. George's University of London
London, Great Britain

Andre Campbell, MD

Professor of Surgery
School of Medicine
University of California San Francisco
San Francisco, California

Diane M. Cappelletty, RPh, PharmD

Associate Professor of Clinical Pharmacy
Chair
Department of Pharmacy Practice
Co-Director
The Infectious Disease Research Laboratory
University of Toledo College of Pharmacy and Pharmaceutical
Sciences
Toledo, Ohio

Joseph A. Carcillo, MD

Associate Professor
Departments of Critical Care Medicine and Pediatrics
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Edward D. Chan, MD

Staff Physician
Pulmonary Section
Denver Veterans Affairs Medical Center
National Jewish Health
Denver, Colorado

Satish Chandrashekar, MD

Assistant Professor of Medicine
Division of Pulmonary, Critical Care, and Sleep Medicine
Lung Transplantation Program
University of Florida College of Medicine
Gainesville, Florida

Lakhmir S. Chawla, MD

Associate Professor of Medicine
George Washington University Medical Center
Washington, DC

David C. Chen, MD

Associate Professor of Clinical Surgery
Department of Surgery
Associate Director of Surgical Education
David Geffen School of Medicine at UCLA
Los Angeles, California

Amit Chopra, MD

Assistant Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Albany Medical College
Albany, New York

Robert S.B. Clark, MD

Professor of Critical Care Medicine
Chief
Pediatric Critical Care Medicine
University of Pittsburgh School of Medicine
Associate Director
Safar Center for Resuscitation Research
Pittsburgh, Pennsylvania

Jonathan D. Cohen, MD, PhD

Robert Bendheim and Lynn Bendheim Thoman Professor in Neuroscience
Professor of Psychology
Princeton University
Co-Director Princeton Neuroscience Institute
Princeton, New Jersey

Stephen M. Cohn, MD, FACS

Witten B. Russ Professor of Surgery
University of Texas Health Science Center
San Antonio, Texas

Kelli A. Cole, PharmD, BCPS

Antibiotic Steward Pharmacist
Department of Pharmacy Services
University of Toledo Medical Center
Toledo, Ohio

Staci Collins, RD, CNSC

Senior Dietitian
Department of Food and Nutrition Services
UC Davis Children's Hospital
Sacramento, California

Gulnur Com, MD

Associate Professor of Clinical Pediatrics
University of Southern California Keck School of Medicine
Los Angeles, California

Chris C. Cook, MD

Assistant Professor of Cardiothoracic Surgery
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Robert N. Cooney, MD, FACS, FCCM

Professor and Chairman
Department of Surgery
SUNY Upstate Medical University
Syracuse, New York

Susan J. Corbridge, PhD, APN

Clinical Associate Professor
College of Nursing and Department of Medicine
Director of Graduate Clinical Studies
College of Nursing
University of Illinois at Chicago
Chicago, Illinois

Thomas C. Corbridge, MD

Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Department of Medicine
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Oliver A. Cornely, MD

Professor of Internal Medicine
Director of Translational Research
Cologne Excellence Cluster on Cellular Stress Responses in Aging-Associated Diseases (CECAD)
Director
Clinical Trials Center Cologne (CTCC)
University of Cologne
Cologne, Germany

Marie L. Crandall, MD, MPH

Professor of Surgery
University of Florida College of Medicine
Jacksonville, Florida

Andrej Čretnik, MD, PhD

Professor of Traumatology
University Clinical Center Maribor
Maribor, Slovenia

David Crippen, MD, FCCM

Professor of Critical Care Medicine
University of Pittsburgh
Pittsburgh, Pennsylvania

Chasen Ashley Croft, MD

Assistant Professor of Surgery
Department of Surgery
University of Florida Health Science Center
Gainesville, Florida

Elliott D. Crouser, MD

Professor of Medicine
Division of Pulmonary, Allergy, Critical Care, and Sleep Medicine
The Ohio State University Wexner Medical Center
Columbus, Ohio

Burke A. Cunha, MD, MACP

Chief
Infectious Disease Division
Winthrop-University Hospital
Mineola, New York
Professor of Medicine
State University of New York School of Medicine
Stony Brook, New York

Cheston B. Cunha, MD

Assistant Professor of Medicine
Division of Infectious Disease
Medical Director
Antimicrobial Stewardship Program
The Warren Alpert Medical School of Brown University
Providence, Rhode Island

J. Randall Curtis, MD, MPH

Professor of Medicine
Division of Pulmonary and Critical Care Medicine
University of Washington School of Medicine
Seattle, Washington

Heidi J. Dalton, MD

Professor of Child Health
University of Arizona College of Medicine
Phoenix, Arizona

Joseph M. Darby, MD

Professor of Critical Care Medicine and Surgery
University of Pittsburgh School of Medicine
Medical Director
Trauma ICU
UPMC-Presbyterian Hospital
Pittsburgh, Pennsylvania

John D. Davies, MA, RRT, FAARC, FCCP

Clinical Research Coordinator
Division of Pulmonary, Allergy, and Critical Care Medicine
Duke University Medical Center
Durham, North Carolina

Jeffrey Dellavolpe, MD, MPH

Critical Care Medicine
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Anne Marie G.A. De Smet, MD, PhD

Anesthesiologist-Intensivist
Afdelingshoofd Intensive Care Volwassenen
Head of Department of Critical Care
University Medical Center Groningen
Groningen, The Netherlands

Anahat Dhillon, MD

Associate Professor
Department of Anesthesiology and Perioperative Medicine
University of California Los Angeles
Los Angeles, California

Rajeev Dhupar, MD

Resident
Division of General Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Rochelle A. Dicker, MD

Professor
Departments of Surgery and Anesthesia
University of California San Francisco
San Francisco, California

Francesca Di Muzio, MD

Department of Anesthesiology and Intensive Care
Agostino Gemelli University Hospital
Università Cattolica del Sacro Cuore
Rome, Italy

Michael N. Diringier, MD

Professor of Neurology and Neurosurgery
Associate Professor of Anesthesiology and Occupational Therapy
Washington University School of Medicine in St. Louis
St. Louis, Missouri

Conrad F. Diven, MD, MS

Assistant Trauma Director
Trauma Research Director
Abrazo West Campus Trauma Center
Goodyear, Arizona

Peter Doelken, MD

Associate Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Albany Medical College
Albany, New York

Michael Donahoe, MD

Professor of Medicine
Division of Pulmonary, Allergy, and Critical Care Medicine
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Caron L. Boyd Dover, MD

Chief
 Cardiothoracic Imaging
 Medical Director of CT
 Assistant Professor of Radiology
 Department of Radiology
 Wake Forest School of Medicine
 Winston Salem, North Carolina

Brian K. Eble, MD

Associate Professor of Pediatrics
 University of Arkansas for Medical Sciences
 Little Rock, Arkansas

Charles L. Edelstein, MD, PhD, FAHA

Professor of Medicine
 Division of Renal Diseases and Hypertension
 University of Colorado Denver
 Aurora, Colorado

Randolph Edwards, MD

Assistant Professor of Surgery
 University of Connecticut School of Medicine
 Surgical Critical Care
 Department of Surgery
 Hartford Hospital
 Hartford, Connecticut

Elwaleed A. Elhassan, MBBS, FACP, FASN

Assistant Professor of Medicine (Nephrology)
 Wayne State University School of Medicine
 Detroit, Michigan

E. Wesley Ely, MD, MPH

Professor of Medicine
 Department of Allergy, Pulmonary, and Critical Care Medicine
 Vanderbilt University Medical Center
 Nashville, Tennessee

Lillian L. Emlet, MD, MS, FACEP, FCCM

Assistant Professor
 Departments of Critical Care Medicine and Emergency Medicine
 Associate Program Director
 IM-CCM Fellowship of the MCCTP
 University of Pittsburgh Medical Center
 Pittsburgh, Pennsylvania

Amir Emtiazjoo, MD, MSc

Assistant Professor of Medicine
 Division of Pulmonary, Critical Care, and Sleep Medicine
 Lung Transplantation Program
 University of Florida College of Medicine
 Gainesville, Florida

Shane W. English, MD, MSc, FRCPC

Associate Scientist
 Clinical Epidemiology Program
 Ottawa Hospital Research Institute
 Assistant Professor of Medicine (Critical Care)
 University of Ottawa
 Intensivist
 Department of Critical Care
 The Ottawa Hospital
 Ottawa, Ontario, Canada

Brent Ershoff, MD

Clinical Instructor
 Department of Anesthesiology and Perioperative Medicine
 David Geffen School of Medicine at UCLA
 Los Angeles, California

Joel H. Ettinger, BS, MHA

President
 Category One Inc.
 Pittsburgh, Pennsylvania

Josh Ettinger, MBA

Category One, Inc.
 Pittsburgh, Pennsylvania

David C. Evans, MD

Assistant Professor of Surgery
 Department of Surgery
 The Ohio State University
 Columbus, Ohio

Gregory T. Everson, MD

Professor of Medicine
 Division of Gastroenterology and Hepatology
 University of Colorado Denver
 Director of Hepatology
 Hepatology and Transplant Center
 University of Colorado Hospital
 Aurora, Colorado

Chiara Faggiano, MD

Department of Anesthesia and Critical Care Medicine
 S. Giovanni Battista Molinette Hospital
 University of Turin
 Turin, Italy

Jeff Fair, MD

Professor
 Department of Surgery
 University of Texas Medical Branch
 Galveston, Texas

Ronald J. Falk, MD

Allen Brewster Distinguished Professor of Medicine
 Director
 UNC Kidney Center
 Chairman
 Department of Medicine
 University of North Carolina
 Chapel Hill, North Carolina

Brenna Farmer, MD

Assistant Professor of Medicine
 Department of Emergency Medicine
 Weill Cornell Medicine of Cornell University
 Assistant Residency Director
 Department of Emergency Medicine
 New York Presbyterian Hospital
 New York, New York

Rory Farnan, MB, BCh, BAO

Division of Cardiology
 Cooper University Hospital
 Camden, New Jersey

Alan P. Farwell, MD

Associate Professor of Medicine
 Chair
 Division of Endocrinology, Diabetes, and Nutrition
 Boston University School of Medicine
 Director
 Endocrine Clinics
 Boston Medical Center
 Boston, Massachusetts

Carinda Feild, PharmD, FCCM

Assistant Dean and Associate Professor
 Department of Pharmacotherapy and Translational Research
 University of Florida College of Pharmacy
 Seminole, Florida

David Feller-Kopman, MD, FACP

Associate Professor of Medicine, Otolaryngology - Head and Neck
 Surgery
 Department of Pulmonary and Critical Care Medicine
 The Johns Hopkins University
 Director
 Bronchoscopy and Interventional Pulmonology
 Johns Hopkins University Medical Institutions
 Baltimore, Maryland

Kathryn Felmet, MD

Assistant Professor
 Departments of Critical Care Medicine and Pediatrics
 University of Pittsburgh School of Medicine
 Pittsburgh, Pennsylvania

Miguel Ferrer, MD, PhD

Department of Pneumology
 Respiratory Institute
 Hospital Clinic
 IDIBAPS
 CibeRes
 Associate Professor
 Department of Medicine
 University of Barcelona
 Barcelona, Spain

Ericka L. Fink, MD, MS

Associate Professor of Critical Care Medicine
 University of Pittsburgh School of Medicine
 Children's Hospital of Pittsburgh of UPMC
 Associate Director
 Safar Center for Resuscitation Research
 Pittsburgh, Pennsylvania

Mitchell P. Fink, MD†

Professor of Surgery and Anesthesiology
 Vice Chair for Critical Care
 Department of Surgery
 David Geffen School of Medicine at UCLA
 Los Angeles, California

Brett E. Fortune, MD

Assistant Professor of Medicine (Digestive Diseases) and of Surgery
 (Transplant)
 Associate Program Director
 Gastroenterology Fellowship
 Yale School of Medicine
 New Haven, Connecticut

Barry I. Freedman, MD

Professor and Chief
 Department of Internal Medicine
 Section on Nephrology
 Wake Forest School of Medicine
 Winston-Salem, North Carolina

Elchanan Fried, MD

Senior Physician
 Department of Medicine
 Hadassah Medical Centers
 Jerusalem, Israel

Kwame Frimpong, MD

Clinical Research Coordinator
 Vanderbilt University Medical Center
 Nashville, Tennessee

Rajeev K. Garg, MD, MS

Assistant Professor of Neurological Sciences and Neurosurgery
 Rush University Medical Center
 Chicago, Illinois

Raúl J. Gazmuri, MD, PhD, FCCM

Professor of Medicine
 Professor of Physiology and Biophysics
 Director
 Resuscitation Institute
 Rosalind Franklin University of Medicine and Science
 Director of Critical Care Medicine
 Captain James A. Lovell Federal Health Care Center
 North Chicago, Illinois

†Deceased.

Robert H. Geelkerken, Prof Dr

Medisch Spectrum Twente
and Faculty of Science and Technology and Experimental Center of
Technical Medicine
University of Twente
Enschede, The Netherlands

Todd W.B. Gehr, MD

Sir Hans A. Krebs Chair of Nephrology
Department of Internal Medicine
Division of Nephrology
Virginia Commonwealth University School of Medicine
Richmond, Virginia

Michael A. Gentile, RRT, FAARC, FCCM

Associate in Research
Division of Pulmonary and Critical Care Medicine
Duke University Medical Center
Durham, North Carolina

M. Patricia George, MD

Assistant Professor of Medicine
University of Pittsburgh School of Medicine
UPMC Montefiore Hospital
Pittsburgh, Pennsylvania

Herwig Gerlach, MD, PhD, MBA

Professor and Chairman
Department of Anesthesia, Intensive Care, and Pain Management
Vivantes-Klinikum Neukölln
Berlin, Germany

Helen Giamarellou, MD, PhD

Professor of Internal Medicine and Infectious Diseases
Hygeia Hospital
Athens, Greece

Fredric Ginsberg, MD

Associate Professor of Medicine
Division of Cardiovascular Disease
Cooper Medical School of Rowan University
Camden, New Jersey

IN MEMORIAM

MITCHELL P. FINK, MD

This edition of the *Textbook of Critical Care* is dedicated to the late Mitchell P. Fink, MD. Dr. Fink was Professor of Surgery and Vice Chair for Critical Care at the University of California Los Angeles and an international leader and giant in the field of critical care medicine. He was the lead author of the Fifth Edition of this textbook. In the Fifth Edition, Dr. Fink inspired a novel, informative, user-friendly, and exciting approach to

revising the textbook that served as the backbone for the Sixth and this new Seventh Edition, which he also importantly helped to formulate. Mitch was a great friend and colleague to each of us, and he will be dearly missed by us and by the entire field. We are confident that his visionary work on this book will serve, through its users, to improve the care and outcomes of critically ill adults and children worldwide for many years into the future.

To my family and friends and all who can contribute to make a better world

— *Jean-Louis Vincent*

To Norma-May, my true love. To Claire and Erin, who bring me the greatest joy,
and to my mother, Dale Abraham, for her support throughout my life

— *Edward Abraham*

To my father, Ernest E. Moore, who was a family practitioner for 50 years in Butler,
Pennsylvania. He inspired me by his dedication to self-education, humility,
and service to his community

— *Frederick A. Moore*

To my family, friends, colleagues, and staff for their sacrifices, support, and
dedication, and to the late Dr. Peter Safar for inspiring each of us to bring promising
new therapies to the bedside of the critically ill

— *Patrick M. Kochanek*

Patients admitted to the intensive care unit (ICU) with critical illness or injury are at risk for neurologic complications.¹⁻⁵ A sudden or unexpected change in the neurologic condition of a critically ill patient often heralds a complication that may cause direct injury to the central nervous system (CNS). Alternatively, such changes may simply be neurologic manifestations of the underlying critical illness or treatment that necessitated ICU admission (e.g., sepsis). These complications can occur in patients admitted to the ICU without neurologic disease and in those admitted for management of primary CNS problems (e.g., stroke). Neurologic complications can also occur as a result of invasive procedures and therapeutic interventions performed. Commonly, recognition of neurologic complications is delayed or missed entirely because ICU treatments (e.g., intubation, drugs) interfere with the physical examination or confound the clinical picture. In other cases, neurologic complications are not recognized because of a lack of sensitive methods to detect the problem (e.g., delirium). Morbidity and mortality are increased among patients who develop neurologic complications; therefore, the intensivist must be vigilant in evaluating all critically ill patients for changes in neurologic status.

Despite the importance of neurologic complications of critical illness, few studies have specifically assessed their incidence and impact on outcome among ICU patients. Available data are limited to medical ICU patients; data regarding neurologic complications in general surgical and other specialty ICU populations must be extracted from other sources. In studies of medical ICU patients, the incidence of neurologic complications is 12.3% to 33%.^{1,2} Patients who develop neurologic complications have increased morbidity, mortality, and ICU length of stay. Sepsis is the most common problem associated with development of neurologic complications (sepsis-associated encephalopathy). In addition to encephalopathy, other common neurologic complications associated with critical illness include seizures and stroke. As the complexity of ICU care has increased, so has the risk of neurologic complications. Neuromuscular disorders are now recognized as a major source of morbidity in severely ill patients.⁶ Recognized neurologic complications occurring in selected medical, surgical, and neurologic ICU populations are shown in Table 1-1.⁷⁻⁴¹

■ IMPAIRMENT IN CONSCIOUSNESS

Global changes in CNS function, best described in terms of impairment in consciousness, are generally referred to as *encephalopathy* or *altered mental status*. An acute change in the level of consciousness, undoubtedly, is the most common neurologic complication that occurs after ICU admission. *Consciousness* is defined as a state of awareness (arousal or wakefulness) and the ability to respond appropriately to changes in environment.⁴² For consciousness to be impaired, global hemispheric dysfunction or dysfunction of the brainstem reticular activating system must be present.⁴³ Altered consciousness may result in a sleeplike state (coma) or a state characterized by confusion and agitation (delirium). States of acutely altered consciousness seen in the critically ill are listed in Table 1-2.

When an acute change in consciousness is noted, the patient should be evaluated, keeping in mind the patient's age, presence or absence of coexisting organ system dysfunction, metabolic status and medication list, and presence or absence of infection. In patients with a primary CNS disorder, deterioration in the level of consciousness (e.g., from

stupor to coma) frequently represents the development of brain edema, increasing intracranial pressure, new or worsening intracranial hemorrhage, hydrocephalus, CNS infection, or cerebral vasospasm. In patients without a primary CNS diagnosis, an acute change in consciousness is often due to the development of infectious complications (i.e., sepsis-associated encephalopathy), drug toxicities, or the development or exacerbation of organ system failure. Nonconvulsive status epilepticus is increasingly being recognized as a cause of impaired consciousness in critically ill patients (Box 1-1).⁴⁴⁻⁵³

States of altered consciousness manifesting as impairment in wakefulness or arousal (i.e., coma and stupor) and their causes are well defined.^{42,43,54,55} Much confusion remains, however, regarding the diagnosis and management of delirium, perhaps the most common state of impaired CNS functioning in critically ill patients at large. When dedicated instruments are used, delirium can be diagnosed in more than 80% of critically ill patients, making this condition the most common neurologic complication of critical illness.⁵⁶⁻⁵⁸ Much of the difficulty in establishing the diagnosis of delirium stems from the belief that delirium is a state characterized mainly by confusion and agitation and that such states are expected consequences of the unique environmental factors and sleep deprivation that characterize the ICU experience. Terms previously used to describe delirium in critically ill patients include *ICU psychosis*, *acute confusional state*, *encephalopathy*, and *postoperative psychosis*. It is now recognized that *ICU psychosis* is a misnomer; *delirium* is a more accurate term.⁵⁹

Currently accepted criteria for the diagnosis of delirium include abrupt onset of impaired consciousness, disturbed cognitive function, fluctuating course, and presence of a medical condition that could impair brain function.⁶⁰ Subtypes of delirium include hyperactive (agitated) delirium and the more common hypoactive or quiet delirium.⁵⁸ Impaired consciousness may be apparent as a reduction in awareness, psychomotor retardation, agitation, or impairment in attention (increased distractibility or vigilance). Cognitive impairment can include disorientation, impaired memory, and perceptual aberrations (hallucinations or illusions).⁶¹ Autonomic hyperactivity and sleep disturbances may be features of delirium in some patients (e.g., those with drug withdrawal syndromes, delirium tremens). Delirium in critically ill patients is associated with increased morbidity, mortality, and ICU length of stay.⁶²⁻⁶⁴ In general, sepsis and medications should be the primary etiologic considerations in critically ill patients who develop delirium.

As has been noted, nonconvulsive status epilepticus is increasingly recognized as an important cause of impaired consciousness in critically ill patients. Although the general term can encompass other entities, such as absence and partial complex seizures, in critically ill patients, *nonconvulsive status epilepticus* is often referred to as *status epilepticus of epileptic encephalopathy*.⁵³ It is characterized by alteration in consciousness or behavior associated with electroencephalographic evidence of continuous or periodic epileptiform activity without overt motor manifestations of seizures. In a study of comatose patients without overt seizure activity, nonconvulsive status epilepticus was evident in 8% of subjects.⁵¹ Nonconvulsive status epilepticus can precede or follow an episode of generalized convulsive status epilepticus; it can also occur in patients with traumatic brain injury, subarachnoid hemorrhage, global brain ischemia or anoxia, sepsis, and multiple organ failure. Despite the general consensus that nonconvulsive status

TABLE 1-1 Neurologic Complications in Selected Specialty Populations

| | |
|---|---|
| MEDICAL | |
| Bone marrow transplantation ^{7,8} | CNS infection, stroke, subdural hematoma, brainstem ischemia, hyperammonemia, Wernicke encephalopathy |
| Cancer ⁹ | Stroke, intracranial hemorrhage, CNS infection |
| Fulminant hepatic failure ¹⁰ | Encephalopathy, coma, brain edema, increased ICP |
| HIV/AIDS ^{11,12} | Opportunistic CNS infection, stroke, vasculitis, delirium, seizures, progressive multifocal leukoencephalopathy |
| Pregnancy ^{13,14} | Seizures, ischemic stroke, cerebral vasospasm, intracranial hemorrhage, cerebral venous thrombosis, hypertensive encephalopathy, pituitary apoplexy |
| SURGICAL | |
| Cardiac surgery ¹⁵⁻¹⁹ | Stroke, delirium, brachial plexus injury, phrenic nerve injury |
| Vascular surgery ^{20,21} | |
| Carotid | Stroke, cranial nerve injuries (recurrent laryngeal, glossopharyngeal, hypoglossal, facial), seizures |
| Aortic | Stroke, paraplegia |
| Peripheral | Delirium |
| Transplantation ^{10,22-25} | |
| Heart | Stroke |
| Liver | Encephalopathy, seizures, opportunistic CNS infection, intracranial hemorrhage, Guillain-Barré syndrome, central pontine myelinolysis |
| Renal | Stroke, opportunistic CNS infection, femoral neuropathy |
| Urologic surgery (TURP) ²⁶ | Seizures and coma (hyponatremia) |
| Otolaryngologic surgery ^{27,28} | Recurrent laryngeal nerve injury, stroke, delirium |
| Orthopedic surgery ²⁹ | |
| Spine | Myelopathy, radiculopathy, epidural abscess, meningitis |
| Knee and hip replacement | Delirium (fat embolism) |
| Long-bone fracture/nailing | Delirium (fat embolism) |
| NEUROLOGIC | |
| Stroke ³⁰⁻³⁴ | Stroke progression or extension, reocclusion after thrombolysis, bleeding, seizures, delirium, brain edema, herniation |
| Intracranial surgery ³⁵ | Bleeding, edema, seizures, CNS infection |
| Subarachnoid hemorrhage ^{32,36-38} | Rebleeding, vasospasm, hydrocephalus, seizures |
| Traumatic brain injury ^{32,39,40} | Intracranial hypertension, bleeding, seizures, stroke (cerebrovascular injury), CNS infection |
| Cervical spinal cord injury ⁴¹ | Ascension of injury, stroke (vertebral artery injury) |

CNS, central nervous system; HIV/AIDS, human immunodeficiency virus/acquired immunodeficiency syndrome; ICP, intracranial pressure; TURP, transurethral prostatic resection.

TABLE 1-2 States of Acutely Altered Consciousness

| STATE | DESCRIPTION |
|-----------|--|
| Coma | Closed eyes, sleeplike state with no response to external stimuli (pain) |
| Stupor | Responsive only to vigorous or painful stimuli |
| Lethargy | Drowsy, arouses easily and appropriately to stimuli |
| Delirium | Acute state of confusion with or without behavioral disturbance |
| Catatonia | Eyes open, unblinking, unresponsive |

epilepticus is a unique entity responsible for impaired consciousness in some critically ill patients, there is no general consensus on the electroencephalographic criteria for its diagnosis or the optimal approach to treatment.⁶⁵

STROKE AND OTHER FOCAL NEUROLOGIC DEFICITS

The new onset of a major neurologic deficit that manifests as a focal impairment in motor or sensory function (e.g., hemiparesis) or one that results in seizures usually indicates a primary problem referable to the cerebrovascular circulation. In a study evaluating the value of computed tomography (CT) in medical ICU patients, ischemic stroke and intracranial bleeding were the most common abnormalities associated with the new onset of a neurologic deficit or seizures.⁶⁶ Overall, the frequency of new-onset stroke is between 1% and 4% in medical ICU patients.^{1,2} Among general surgical patients, the frequency of

perioperative stroke ranges from 0.3% to 3.5%.⁶⁷ Patients undergoing cardiac or vascular surgery and surgical patients with underlying cerebrovascular disease can be expected to have an increased risk of perioperative stroke.¹⁹

The frequency of new or worsening focal neurologic deficits in patients admitted with a primary neurologic or neurosurgical disorder varies. For example, as many as 30% of patients with aneurysmal subarachnoid hemorrhage develop delayed ischemic neurologic deficits.³⁶ Patients admitted with stroke often develop worsening or new symptoms as a result of stroke progression, bleeding, or reocclusion of vessels previously opened with interventional therapy. In patients who have undergone elective intracranial surgery, postsurgical bleeding or infectious complications are the main causes of new focal deficits. In trauma patients, unrecognized injuries to the cerebrovascular circulation can cause new deficits. Patients who have sustained spinal cord injuries, and those who have undergone surgery of the spine or of the thoracic or abdominal aorta, can develop worsening or new symptoms of spinal cord injury. Early deterioration of CNS function after spinal cord injury usually occurs as a consequence of medical interventions to stabilize the spine, whereas late deterioration is usually due to hypotension and impaired cord perfusion. Occasionally, focal weakness or sensory symptoms in the extremities occur as a result of occult brachial plexus injury or compression neuropathy. New cranial nerve deficits in patients without primary neurologic problems can occur after neck surgery or carotid endarterectomy.

SEIZURES

The new onset of motor seizures occurs in 0.8% to 4% of critically ill medical ICU patients.^{1,2,68} New-onset seizures in general medical-surgical ICU patients is typically caused by narcotic withdrawal, hyponatremia, drug toxicities, or previously unrecognized structural abnormalities.^{3,68} New stroke, intracranial bleeding, and CNS infection

BOX 1-1**General Causes of Acutely Impaired Consciousness in the Critically Ill****INFECTION**

Sepsis encephalopathy
CNS infection

DRUGS

Narcotics
Benzodiazepines
Anticholinergics
Anticonvulsants
Tricyclic antidepressants
Selective serotonin uptake inhibitors
Phenothiazines
Steroids
Immunosuppressants (cyclosporine, FK506, OKT3)
Anesthetics

ELECTROLYTE AND ACID-BASE DISTURBANCES

Hyponatremia
Hypernatremia
Hypercalcemia
Hypermagnesemia
Severe acidemia and alkalemia

ORGAN SYSTEM FAILURE

Shock
Renal failure
Hepatic failure
Pancreatitis
Respiratory failure (hypoxia, hypercapnia)

ENDOCRINE DISORDERS

Hypoglycemia
Hyperglycemia
Hypothyroidism
Hyperthyroidism
Pituitary apoplexy

DRUG WITHDRAWAL

Alcohol
Opiates
Barbiturates
Benzodiazepines

VASCULAR CAUSES

Shock
Hypotension
Hypertensive encephalopathy
CNS vasculitis
Cerebral venous sinus thrombosis

CNS DISORDERS

Hemorrhage
Stroke
Brain edema
Hydrocephalus
Increased intracranial pressure
Meningitis
Ventriculitis
Brain abscess
Subdural empyema
Seizures
Vasculitis

SEIZURES

Convulsive and nonconvulsive status epilepticus

MISCELLANEOUS

Fat embolism syndrome
Neuroleptic malignant syndrome
Thiamine deficiency (Wernicke encephalopathy)
Psychogenic unresponsiveness

CNS, central nervous system.

are other potential causes of seizures after ICU admission. The frequency of seizures is higher in patients admitted to the ICU with a primary neurologic problem such as traumatic brain injury, aneurysmal subarachnoid hemorrhage, stroke, or CNS infection.⁶⁹ Because nonconvulsive status epilepticus may be more common than was previously appreciated, this problem should also be considered in the differential diagnosis of patients developing new, unexplained, or prolonged alterations in consciousness.

GENERALIZED WEAKNESS AND NEUROMUSCULAR DISORDERS

Generalized muscle weakness often becomes apparent in ICU patients as previous impairments in arousal are resolving or sedative and neuromuscular blocking agents are being discontinued or tapered. Polyneuropathy and myopathy associated with critical illness are now well recognized as the principal causes of new-onset generalized weakness among ICU patients being treated for nonneuromuscular disorders.^{5,70-73} These disorders also may be responsible for prolonged ventilator dependency in some patients. Patients at increased risk for these complications include those with sepsis, systemic inflammatory response syndrome, and multiple organ dysfunction syndrome, as well as those who require prolonged mechanical ventilation. Other risk factors include treatment with corticosteroids or neuromuscular blocking agents. In contrast to demyelinating neuropathies (e.g., Guillain-Barré syndrome), critical illness polyneuropathy is primarily an axonal condition. Critical illness polyneuropathy is diagnosed in a high percentage of patients undergoing careful evaluation for weakness acquired while in the ICU. Because primary myopathy coexists in a large number of patients with critical illness polyneuropathy, *ICU-acquired paresis*⁷² or *critical illness neuromuscular abnormalities*⁵ may be better terms to describe this problem. Although acute Guillain-Barré syndrome and myasthenia gravis are rare complications of critical illness, these diagnoses should also be considered in patients who develop generalized weakness in the ICU.

NEUROLOGIC COMPLICATIONS OF PROCEDURES AND TREATMENTS

Routine procedures performed in the ICU or in association with evaluation and treatment of critical illness can result in neurologic complications.⁴ The most obvious neurologic complications are those associated with intracranial bleeding secondary to the treatment of stroke and other disorders with thrombolytic agents or anticoagulants. Other notable complications are listed in Table 1-3.

EVALUATION OF SUDDEN NEUROLOGIC CHANGE

A new or sudden change in the neurologic condition of a critically ill patient necessitates a focused neurologic examination, review of the clinical course and medications administered before the change, a thorough laboratory assessment, and appropriate imaging or neurophysiologic studies when indicated. The type and extent of the evaluation depend on clinical context and the general category of neurologic change occurring. The history and physical examination should lead the clinician to the diagnostic approach best suited to the individual patient.

Essential elements of the neurologic examination include an assessment of the level and content of consciousness, pupillary size and reactivity, and motor function. Additional evaluation of the cranial nerves and peripheral reflexes and a sensory examination are conducted as indicated by the clinical circumstances. If the patient is comatose on initial evaluation, a more detailed coma examination should be performed to help differentiate structural from metabolic causes of coma.^{43,55} When the evaluation reveals only a change in arousal without evidence of a localizing lesion in the CNS, a search for infection, discontinuation or modification of drug therapy, and a

TABLE 1-3 Neurologic Complications Associated with ICU Procedures and Treatments

| PROCEDURE | COMPLICATION |
|------------------------------------|--|
| Angiography | Cerebral cholesterol emboli syndrome |
| Anticoagulants/antiplatelet agents | Intracranial bleeding |
| Arterial catheterization | Cerebral embolism |
| Bronchoscopy | Increased ICP |
| Central venous catheterization | Cerebral air embolism, carotid dissection, Horner's syndrome, phrenic nerve injury, brachial plexus injury, cranial nerve injury |
| DC cardioversion | Embolic stroke, seizures |
| Dialysis | Seizures, increased ICP (dialysis disequilibrium syndrome) |
| Endovascular procedures (CNS) | Vessel rupture, thrombosis, reperfusion bleeding |
| Epidural catheter | Spinal epidural hematoma, epidural abscess |
| ICP monitoring | CNS infection (ventriculitis), hemorrhage |
| Intraaortic balloon pump | Lower extremity paralysis |
| Intubation | Spinal cord injury |
| Left ventricular assist devices | Stroke, seizures |
| Lumbar puncture or drain | Meningitis, herniation |
| Mechanical ventilation | Cerebral air embolism, increased ICP (high PEEP and hypercapnia), seizures (hypocapnia) |
| Nasogastric intubation | Intracranial placement |

CNS, central nervous system; DC, direct current; ICP, intracranial pressure; ICU, intensive care unit; PEEP, positive end-expiratory pressure.

general metabolic evaluation may be indicated. Lumbar puncture to aid the diagnosis of CNS infection may be warranted in selected neurosurgical patients and immunocompromised individuals. Lumbar puncture to rule out nosocomially acquired meningitis in other patients is generally not rewarding.⁷⁴ Electroencephalography should be performed in patients with clear evidence of seizures, as well as

when the diagnosis of nonconvulsive status epilepticus is being entertained. Continuous electroencephalography should be considered when the index of suspicion for nonconvulsive status epilepticus remains high and the initial electroencephalographic studies are unrevealing.

Computed tomography (CT) is indicated for nonneurologic patients with new focal deficits, seizures, or otherwise unexplained impairments in arousal.⁶⁶ In patients with primary neurologic disorders, CT is indicated if worsening brain edema, herniation, bleeding, and hydrocephalus are considerations when new deficits or worsening neurologic status occurs. In some cases, when the basis for a change in neurologic condition remains elusive, magnetic resonance imaging (MRI) may be helpful. In particular, the diffusion-weighted MRI technique can reveal structural abnormalities such as hypoxic brain injury, fat embolism, vasculitis, cerebral venous thrombosis, or multiple infarcts following cardiopulmonary bypass that are not apparent by standard CT or conventional MRI.⁷⁵⁻⁸⁰ MRI may be the imaging modality of choice in patients with human immunodeficiency virus (HIV) and new CNS complications.⁷⁵ For patients who develop signs and symptoms of spinal cord injury complicating critical illness, MRI or somatosensory evoked potentials can be used to further delineate the nature and severity of the injury. For patients who develop generalized muscle weakness or unexplained ventilator dependency, electromyography and nerve conduction studies can confirm the presence of critical illness polyneuropathy or myopathy.

MONITORING FOR NEUROLOGIC CHANGES

The common occurrence of neurologic changes in critically ill patients emphasizes the need for vigilant monitoring. A variety of clinical techniques such as the Glasgow Coma Scale, National Institutes of Health Stroke Scale, Ramsay Sedation Scale, Richmond Agitation-Sedation Scale, and Confusion Assessment Method for the Intensive Care Unit (CAM-ICU) can be used to monitor clinical neurologic status.^{57,58,81-86} Neurophysiologic methods such as the bispectral index may provide more objective neurologic monitoring in the future for patients admitted to the ICU with and without primary neurologic problems.⁸⁷⁻⁸⁹ For patients admitted to the ICU with a primary neurologic disorder, a variety of monitoring techniques including measurements of intracranial pressure, near-infrared spectroscopy, brain tissue PO_2 , transcranial Doppler, and electroencephalography are available.⁹⁰

Agitation and delirium are commonly encountered in the intensive care unit (ICU). They are more than just an inconvenience; these conditions can have deleterious effects on patient and staff safety and contribute to poor outcomes. It is therefore important for clinicians to be able to recognize agitation and delirium and to have an organized approach for its evaluation and management.

■ AGITATION

Agitation is a psychomotor disturbance characterized by excessive motor activity associated with a feeling of inner tension.^{1,3} The activity is usually nonproductive and repetitious, consisting of behaviors such as pacing, fidgeting, wringing of hands, pulling of clothes, and an inability to sit still. Careful observation of the patient may reveal the underlying intent. In the ICU, agitation is frequently related to anxiety or delirium. Agitation may be caused by various factors: metabolic disorders (hypo- and hypernatremia), hyperthermia, hypoxia, hypotension, use of sedative drugs and/or analgesics, sepsis, alcohol withdrawal, and long-term psychoactive drug use to name a few.^{4,5} It can also be caused by external factors such as noise, discomfort, and pain.⁶ Associated with a longer length of stay in the ICU and higher costs,⁴ agitation can be mild, characterized by increased movements and an apparent inability to get comfortable, or it can be severe. Severe agitation can be life threatening, leading to higher rates of self-extubation, self-removal of catheters and medical devices, nosocomial infections,⁴ hypoxia, barotrauma, and/or hypotension due to patient/ventilator asynchrony. Indeed, recent studies have shown that agitation contributes to ventilator asynchrony, increased oxygen consumption, and increased production of CO₂ and lactic acid; these effects can lead to life-threatening respiratory and metabolic acidosis.⁵

■ DELIRIUM

Delirium can be defined as follows: (1) A disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention. (2) A change in cognition (e.g., memory deficit, disorientation, language disturbance) or development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia. (3) The disturbance develops over a short period (usually hours to days) and tends to fluctuate during the course of the day. (4) There is evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiologic consequence of a general medical condition, an intoxicating substance, medication use, or more than one cause (Fig. 2-1).³ Delirium is commonly underdiagnosed in the ICU and has a reported prevalence of 20% to 80%, depending on the severity of illness and the need for mechanical ventilation.⁷⁻¹⁰ Recent investigations have shown that the presence of delirium is a strong predictor of longer hospital stay, higher costs, and increased risk of death.¹¹⁻¹³ Each additional day with delirium increases a patient's risk of dying by 10%.¹⁴ Longer periods of delirium are also associated with greater degrees of cognitive decline when patients are evaluated after one year.¹³ Thus, delirium can adversely affect the quality of life in survivors of critical illnesses and may serve as an intermediate recognizable step for targeting therapies to prevent poor outcomes in survivors of critical illness.^{13,15}

Unfortunately, the true prevalence and magnitude of delirium have been poorly documented because myriad terms including *acute confusional state*, *ICU psychosis*, *acute brain dysfunction*, and *encephalopathy*,

have been used to describe this condition.¹⁶ Delirium can be classified according to psychomotor behavior into hypoactive delirium, hyperactive delirium, or a mixed subtype. Hypoactive delirium, which is the most prevalent form of delirium, is characterized by decreased physical and mental activity and inattention. In contrast, hyperactive delirium is characterized by combativeness and agitation. Patients with both features have mixed delirium.¹⁷⁻¹⁹ Hyperactive delirium puts both patients and caregivers at risk of serious injury but fortunately only occurs in a minority of critically ill patients.¹⁷⁻¹⁹ Hypoactive delirium might actually be associated with a worse prognosis.^{20,21} The Delirium Motor Subtype Scale may assist in making this diagnosis.²²

Although healthcare professionals realize the importance of recognizing delirium, it frequently goes unrecognized in the ICU.²³⁻³⁰ Even when ICU delirium is recognized, most clinicians consider it an expected event that is often iatrogenic and without consequence.²³ However, it needs to be viewed as a form of organic brain dysfunction that has consequences if left undiagnosed and untreated.

Risk Factors for Delirium

The risk factors for agitation and delirium are many and overlap to a large extent (Table 2-1). Fortunately there are several mnemonics that can aid clinicians in recalling the list; two common ones are IWATCH-DEATH and DELIRIUM (Table 2-2). In practical terms, risk factors can be divided into three categories: the acute illness itself, patient factors, and iatrogenic or environmental factors. Importantly, a number of medications that are commonly used in the ICU are associated with the development of agitation and delirium (Box 2-1). A thorough approach to the treatment and support of the acute illness (e.g., controlling sources of sepsis and giving appropriate antibiotics; correcting hypoxia, metabolic disturbances, dehydration, and hyperthermia; normalizing sleep/wake cycles), as well as minimizing iatrogenic factors (e.g., excessive sedation), can reduce the incidence and/or severity of delirium and its attendant complications. A retrospective study conducted on postoperative delirium, specifically in patients undergoing cardiopulmonary bypass, has alluded to a decreased incidence of delirium in patients pre-treated with statins.³¹ Furthermore, ICU statins have been associated with decreased delirium, most significantly in the early stages of sepsis; in contrast to this, discontinuation of statins has been shown to be associated with increased delirium.^{32,33}

■ PATHOPHYSIOLOGY

The pathophysiology of delirium is poorly understood, although there are a number of hypotheses:

- **Neurotransmitter imbalance.** Multiple neurotransmitters have been implicated, including dopamine (excess), acetylcholine (relative depletion), γ -aminobutyric acid (GABA), serotonin, endorphins, norepinephrine, and glutamate.³⁴⁻³⁷
- **Inflammatory mediators.** Inflammatory mediators, such as tumor necrosis factor alpha (TNF- α), interleukin-1 (IL-1), and other cytokines and chemokines, have been implicated in the pathogenesis of endothelial damage, thrombin formation, and microvascular dysfunction in the central nervous system (CNS), contributing to delirium.³⁷ Recently, a study in the ICU has strengthened the evidence of a role for endothelial dysfunction in increasing the duration of delirium.³⁸

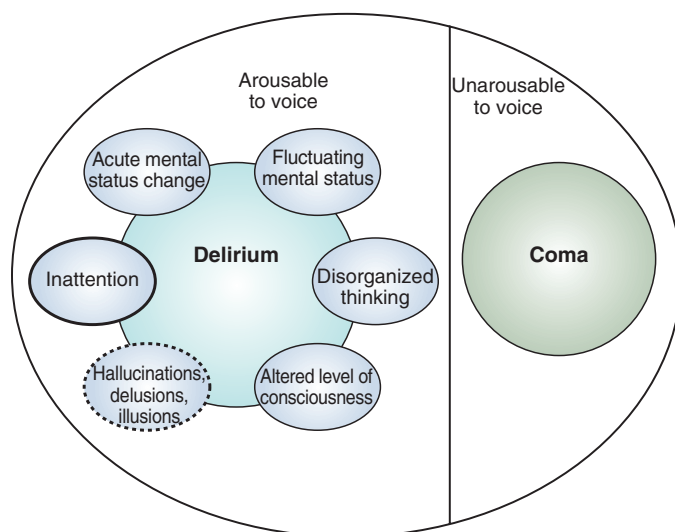

FIGURE 2-1 ■ Acute brain dysfunction. Patients who are unresponsive to voice are considered to be in a coma. Patients who respond to voice can be further evaluated for delirium using validated delirium monitoring instruments. Inattention is a cardinal feature of delirium. Other pivotal features include a change in mental status that fluctuates over hours to days, disorganized thinking, and altered levels of consciousness. While hallucinations, delusions, and illusions may be part of the perceptual disturbances seen in delirium, they on their own are not synonymous with delirium, a diagnosis of which requires the presence of inattention and other pivotal features outlined above. (With permission from E. Wesley Ely and A. Morandi) (www.icudelirium.org).

TABLE 2-1 Risk Factors for Agitation and Delirium

| | |
|--|---------------------------------------|
| Age >70 years | BUN/creatinine ratio ≥ 18 |
| Transfer from a nursing home | Renal failure, creatinine > 2.0 mg/dL |
| History of depression | Liver disease |
| History of dementia, stroke, or epilepsy | CHF |
| Alcohol abuse within past month | Cardiogenic or septic shock |
| Tobacco use | Myocardial infarction |
| Drug overdose or illicit drug use | Infection |
| HIV infection | CNS pathology |
| Psychoactive medications | Urinary retention or fecal impaction |
| Hypo- or hypernatremia | Tube feeding |
| Hypo- or hyperglycemia | Rectal or bladder catheters |
| Hypo- or hyperthyroidism | Physical restraints |
| Hypothermia or fever | Central line catheters |
| Hypertension | Malnutrition or vitamin deficiencies |
| Hypoxia | Procedural complications |
| Acidosis or alkalosis | Visual or hearing impairment |
| Pain | Sleep disruption |
| Fear and anxiety | |

BUN, blood urea nitrogen; CHF, congestive heart failure; CNS, central nervous system; HIV, human immunodeficiency virus.

- **Impaired oxidative metabolism.** According to this hypothesis, delirium is a result of cerebral insufficiency secondary to a global failure in oxidative metabolism.³⁹
- **Large neutral amino acids.** Increased cerebral uptake of tryptophan and tyrosine can lead to elevated levels of serotonin,

TABLE 2-2 Mnemonic for Risk Factors for Delirium and Agitation

IWATCHDEATH

Infection
Withdrawal
Acute metabolic
Trauma/pain
Central nervous system pathology
Hypoxia
Deficiencies (vitamin B₁₂, thiamine)
Endocrinopathies (thyroid, adrenal)
Acute vascular (hypertension, shock)
Toxins/drugs
Heavy metals

DELIRIUM

Drugs
Electrolyte and physiologic abnormalities
Lack of drugs (withdrawal)
Infection
Reduced sensory input (blindness, deafness)
Intracranial problems (CVA, meningitis, seizure)
Urinary retention and fecal impaction
Myocardial problems (MI, arrhythmia, CHF)

CHF, congestive heart failure; CVA, cerebrovascular accident; MI, myocardial infarction.

BOX 2-1

Commonly Used Drugs Associated With Delirium and Agitation

Benzodiazepines
Opiates (especially meperidine)
Anticholinergics
Antihistamines
H₂ blockers
Antibiotics
Corticosteroids
Metoclopramide

dopamine, and norepinephrine in the CNS. Altered availability of these amino acids is associated with increased risk of development of delirium.⁴⁰

ASSESSMENT

Recently, the Society of Critical Care Medicine (SCCM) published guidelines for the use of sedatives and analgesics in the ICU.⁴¹ The SCCM has recommended the routine monitoring of pain, anxiety, and delirium and the documentation of responses to therapy for these conditions.⁴²

There are many scales available for the assessment of agitation and sedation, including the Ramsay Scale,⁴³ the Riker Sedation-Agitation Scale (SAS),⁴⁴ the Motor Activity Assessment Scale (MAAS),⁴⁵ the Richmond Agitation-Sedation Scale (RASS),⁴⁶ the Adaptation to Intensive Care Environment (ATICE)⁴⁷ scale, and the Minnesota Sedation Assessment Tool (MSAT).⁴⁷ Most of these scales have good reliability and validity among adult ICU patients and can be used to set targets for goal-directed sedative administration. The SAS, which scores agitation and sedation using a 7-point system, has excellent inter-rater reliability (kappa = 0.92) and is highly correlated ($r^2 = 0.83$ to 0.86) with other scales. The RASS (Table 2-3), however, is the only method shown to detect variations in the level of consciousness over time or in response to changes in sedative and analgesic drug use.⁴⁸ The 10-point RASS scale has discrete criteria to distinguish levels of agitation and sedation. The evaluation of patients consists of a 3-step process. First, the patient is observed to determine whether he or she is alert, restless, or agitated (0 to +4). Second, if the patient is not alert and does not show positive motoric characteristics, the patient's name is called and his or her sedation level scored based on the duration of eye contact (−1 to −3). Third, if there is no eye opening on verbal

TABLE 2-3 Richmond Agitation-Sedation Scale

| | | |
|----|-------------------|--|
| +4 | Combative | Combative, violent, immediate danger to staff |
| +3 | Very agitated | Pulls or removes tube(s) or catheter(s); aggressive |
| +2 | Agitated | Frequent nonpurposeful movement; fights ventilator |
| +1 | Restless | Anxious, apprehensive, but movements not aggressive or vigorous |
| 0 | Alert and calm | |
| −1 | Drowsy | Not fully alert but has sustained (>10 sec) awakening (eye opening/contact) to voice |
| −2 | Light sedation | Drowsy; briefly (<10 sec) awakens to voice or physical stimulation |
| −3 | Moderate sedation | Movement or eye opening (but no eye contact) to voice |
| −4 | Deep sedation | No response to voice, but movement or eye opening to physical stimulation |
| −5 | Unarousable | No response to voice or physical stimulation |

PROCEDURE FOR ASSESSMENT

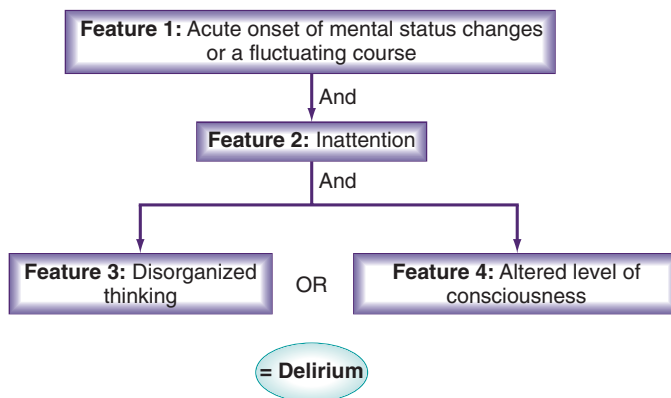

1. Observe patient. Is patient alert, restless, or agitated? (Score 0 to +4)
2. If not alert, state patient's name and tell him or her to open eyes and look at speaker. Patient awakens, with sustained eye opening and eye contact. (Score −1)
3. Patient awakens, with eye opening and eye contact, but not sustained. (Score −2)
4. Patient does not awaken (no eye contact) but has eye opening or movement in response to voice. (Score −3)
3. Physically stimulate patient by shaking shoulder and/or rubbing sternum. No response to voice, but response (movement) to physical stimulation. (Score −4)
4. No response to voice or physical stimulation (Score −5)

From Sessler CN, Gosnell MS, Grap MJ, et al. The Richmond Agitation-Sedation Scale: validity and reliability in adult intensive care unit patients. *Am J Respir Crit Care Med* 2002;166(10):1338-1344.

stimulation, the patient's shoulder is shaken or pressure applied over the sternum by rubbing, and the response noted (−4 or −5). This assessment takes less than 20 seconds in total and correlates well with other measures of sedation (e.g., Glasgow Coma Scale [GCS], bispectral electroencephalography, and neuropsychiatric ratings).⁴⁶

Until recently, there was no valid and reliable way to assess delirium in critically ill patients, many of whom are nonverbal owing to sedation or mechanical ventilation.^{51,58} A number of tools have been developed to aid in the detection of delirium in the ICU. These tools have been validated for use in both intubated and nonintubated patients and measured against a "gold standard," the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) criteria. The tools are the Confusion Assessment Method for the ICU (CAM-ICU)⁵¹⁻⁵⁵ and the Intensive Care Delirium Screening Checklist (ICDSC).⁸

The CAM-ICU (Fig. 2-2) is a delirium measurement tool developed by a team of specialists in critical care, psychiatry, neurology, and geriatrics.^{51,58} Administered by a nurse, the evaluation takes only 1 to 2 minutes to conduct and is 98% accurate in detecting delirium as compared with a full DSM-V assessment by a geriatric psychiatrist.^{51,52}

**FIGURE 2-2** ■ Confusion Assessment Method in the Intensive Care Unit (CAM-ICU).**TABLE 2-4 Intensive Care Delirium Screening Checklist****PATIENT EVALUATION**

| Altered level of consciousness | (A–E)* |
|--------------------------------------|--|
| Inattention | Difficulty in following a conversation or instructions. Easily distracted by external stimuli. Difficulty in shifting focus. Any of these scores 1 point. |
| Disorientation | Any obvious mistake in time, place, or person scores 1 point. |
| Hallucinations-delusions-psychosis | The unequivocal clinical manifestation of hallucination or behavior probably attributable to hallucination or delusion. Gross impairment in reality testing. Any of these scores 1 point. |
| Psychomotor agitation or retardation | Hyperactivity requiring the use of additional sedative drugs or restraints to control potential danger to self or others. Hypoactivity or clinically noticeable psychomotor slowing. |
| Inappropriate speech or mood | Inappropriate, disorganized, or incoherent speech. Inappropriate display of emotion related to events or situation. Any of these scores 1 point. |
| Sleep/wake cycle disturbance | Sleeping less than 4 h or waking frequently at night (do not consider wakefulness initiated by medical staff or loud environment). Sleeping during most of the day. Any of these scores 1 point. |
| Symptom fluctuation | Fluctuation of the manifestation of any item or symptom over 24 h scores 1 point. |

Total Score (0-8)

*Level of consciousness:

A—No response: score 0.

B—Response to intense and repeated stimulation (loud voice and pain): score 0.

C—Response to mild or moderate stimulation: score 1.

D—Normal wakefulness: score 0.

E—Exaggerated response to normal stimulation: score 1.

Available at: <http://www.acgme.org/acgme/web/tabid/445/GraduateMedicalEducation/SingleAccreditationSystemforAOA-ApprovedPrograms.aspx>. Accessed November 12.

To perform the CAM-ICU, patients are first evaluated for level of consciousness; patients who respond to verbal commands (a RASS score of −3 or higher level of arousal) can then be assessed for delirium. The CAM-ICU comprises four features: (1) a change in mental status from baseline or a fluctuation in mental status, (2) inattention, (3) disorganized thinking, and (4) altered level of consciousness. Delirium is diagnosed if patients have features 1 and 2, and either feature 3 or 4 is positive (see Fig. 2-2).

The ICDSC⁸ (Table 2-4) is a checklist-based assessment tool that evaluates inattention, disorientation, hallucination, delusion or

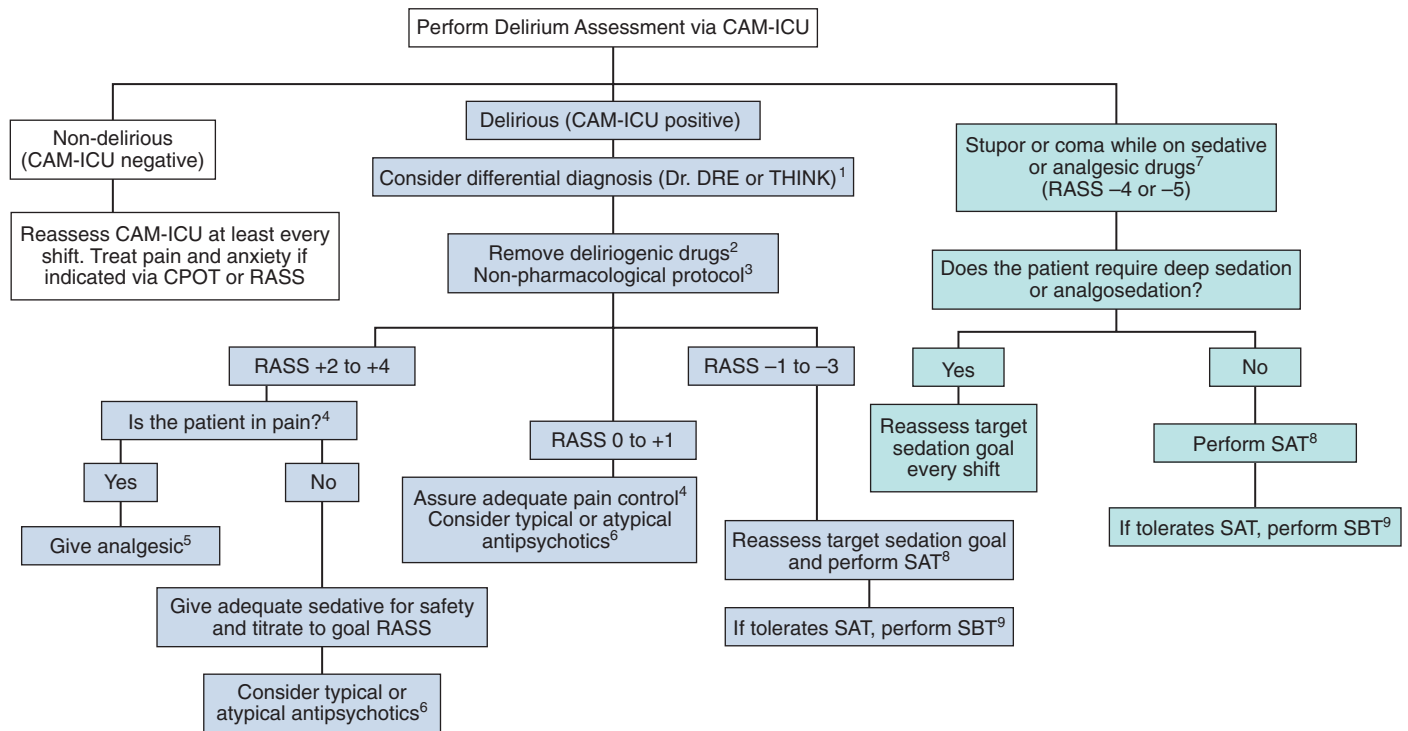

psychosis, psychomotor agitation or retardation, inappropriate speech or mood, sleep/wake cycle disturbances, and fluctuations in these symptoms. Each of the eight items is scored as absent or present (0 or 1), respectively, and summed. A score of 4 or above indicates delirium, while 0 indicates no delirium. Patients with scores between 1 and 3 are considered to have subsyndromal delirium,⁵⁹ which has worse prognostic implications than the absence of delirium but a better prognosis than clearly present delirium.

Recent studies have called into question the usefulness of delirium evaluations for patients under sedation.^{60,61} A small subset of patients (approximately 10%) were noted to have rapidly reversible sedation-related delirium, but unfortunately in this study the majority of patients

continued to have persistent delirium even after interruption of sedation. Thus, when feasible, delirium evaluation should be performed after interruption of sedation; however delirium evaluations should not be forgone just because a patient is under sedation since the omission of the diagnosis would be far worse than overdiagnosing delirium in a handful of patients.

MANAGEMENT

The development of effective evidence-based strategies and protocols for prevention and treatment of delirium awaits data from ongoing randomized clinical trials of both nonpharmacologic and

1. Dr. DRE:
Diseases: Sepsis, CHF, COPD
Drug Removal: SATs and stopping benzodiazepines/narcotics
Environment: Immobilization, sleep and day/night orientation, hearing aids, eye glasses, noise
THINK:
Toxic Situations – CHF, shock, dehydration – Deliriogenic meds (tight titration) – New organ failure (liver, kidney, etc.)
Hypoxemia
Infection/sepsis (nosocomial), immobilization
Nonpharmacological interventions³
K⁺ or Electrolyte problems
2. Consider stopping or substituting deliriogenic medications such as benzodiazepines, anticholinergic medications (metoclopramide, H2 blockers, promethazine, diphenhydramine), steroids, etc.
3. See non-pharmacological protocol – see below.
4. If patient is non-verbal assess via CPOT, or if patient is verbal assess via visual analog scale.
5. Analgesia – Adequate pain control may decrease delirium. Consider opiates, non-steroidals, acetaminophen, or gabapentin (neuropathic pain).
6. Typical or atypical antipsychotics. Discontinue if high fever, QTc prolongation, or drug-induced rigidity.
7. Consider non-benzodiazepine sedation strategies (propofol or dexmedetomidine)
8. Spontaneous Awakening Trial (SAT) – If meets safety criteria (no active seizures, no alcohol withdrawal, no agitation, no paralytics, no myocardial ischemia, normal intracranial pressure, $\text{FiO}_2 \leq 70\%$)
9. Spontaneous Breathing Trial (SBT) – If meets safety criteria (no agitation, no myocardial ischemia, $\text{FiO}_2 \leq 50\%$, adequate inspiratory efforts, O_2 saturation $\geq 88\%$, no vasopressor use, PEEP ≤ 7.5 cm)

Non-pharmacological protocol³

Orientation

Provide visual and hearing aids
Encourage communication and reorient patient repetitively. Have familiar objects from patient's home in the room
Attempt consistency in nursing staff
Family engagement and empowerment

Environment

Sleep hygiene: Lights off at night, on during day.
Control excess noise (staff, equipment), earplugs
Early mobilization and exercise
Music

Clinical parameters

Maintain systolic blood pressure > 90 mm Hg
Maintain oxygen saturations $> 90\%$
Treat underlying metabolic derangements and infections

FIGURE 2-3 ■ Delirium Protocol as a part of ABCDEF Bundle.

pharmacologic strategies. Refer to Chapter 51 for a detailed description of management strategies of delirium, including an empiric sedation and delirium protocol. A brief overview is provided here.

When agitation or delirium develops in a previously comfortable patient, a search for the underlying cause should be undertaken before attempting pharmacologic intervention. A rapid assessment should be performed, including assessment of vital signs and physical examination to rule out life-threatening problems (e.g., hypoxia, self-extubation, pneumothorax, hypotension), or other acutely reversible physiologic causes (e.g., hypoglycemia, metabolic acidosis, stroke, seizure, pain). The previously mentioned IWATCHDEATH and DELIRIUM mnemonics can be particularly helpful in guiding this initial evaluation.

Once life-threatening causes are ruled out as possible etiologies, aspects of good patient care such as reorienting patients, improving sleep and hygiene, providing visual and hearing aids if previously used, removing medications that can provoke delirium, and decreasing the use of invasive devices if not required (e.g., bladder catheters, restraints), should be undertaken.

The use of ABCDEs (Awakening and Breathing Trials, Choice of appropriate sedation, Delirium monitoring and management, and Early mobility and Exercise) has been shown to decrease the incidence of delirium and improve patient outcome (Fig. 2-3). This algorithm based on the PAD 2013 guidelines⁴¹ involves the following: (1) Routine *assessment* of agitation, depth and quality of sedation and delirium using appropriate scales (RASS and SAS for agitation and sedation and CAM-ICU or ICDSC for delirium). They recommend using protocol target-based sedation and targeting the lightest possible sedation, thus exposing the patient to lower cumulative doses of sedatives⁶² and/or daily awakening trials⁶³ and spontaneous breathing trials⁶⁴ to reduce the total time spent on mechanical ventilation. Coordination of daily awakening and daily breathing was associated with shorter durations of mechanical ventilation, reduction in length of hospital stay, and no long-term neuropsychologic consequences of waking patients during critical illness.^{65,66} (2) *Treatment* should start with treating analgesia first. Choosing the right sedative regimen in critically ill patients is important. Numerous studies have confirmed that benzodiazepines are associated with poor clinical outcomes.^{67,68,69} The guidelines also recommend avoiding rivastigmine and antipsychotics if there is an increased risk of Torsades de Pointes. (3) *Prevention* also plays an important role. Exercise and early mobility in ICU patients is associated with decreased length of both ICU and hospital polypharmacy.^{70,71} Risk factors for delirium need to be identified and eliminated. Promoting sleep and restarting baseline antipsychotic medications are also important. Data from the Maximizing Efficacy of Targeted Sedation and Reducing Neurological Dysfunction (MENDS)⁶⁷ study and the Safety and Efficacy of Dexmedetomidine Compared to Midazolam (SEDCOM) trial⁶⁹ also support the view

that dexmedetomidine can decrease the duration and prevalence of delirium when compared to lorazepam or midazolam. Pharmacologic therapy should be attempted only after correcting any contributing factors or underlying physiologic abnormalities. Although these agents are intended to improve cognition, they all have psychoactive effects that can further cloud the sensorium and promote a longer overall duration of cognitive impairment. Patients who manifest delirium should be treated with traditional antipsychotic medication. Newer “atypical” antipsychotic agents (e.g., risperidone, ziprasidone, quetiapine, olanzapine) may decrease the duration of delirium.⁷⁶

Benzodiazepines are not recommended for the management of delirium because they can paradoxically exacerbate delirium. These drugs can also promote oversedation and respiratory suppression. However, they remain the drugs of choice for the treatment of delirium tremens (and other withdrawal syndromes), and seizures.

At times, mechanical restraints may be needed to ensure the safety of patients and staff while waiting for medications to take effect. It is important to keep in mind, however, that restraints can increase agitation and delirium, and their use may have adverse consequences, including strangulation, nerve injury, skin breakdown, and other complications of immobilization.

SUMMARY

Agitation and delirium are very common in the ICU, where their occurrence puts patients at risk of self-injury and poor clinical outcomes. Available sedation and delirium monitoring instruments allow clinicians to recognize these forms of brain dysfunction. Through a systematic approach, life-threatening problems and other acutely reversible physiologic causes can be rapidly identified and remedied. A strategy that focuses on early liberation from mechanical ventilation and early mobilization can help reduce the burden of delirium. Use of antipsychotics should be reserved for patients who pose an imminent risk to themselves or staff.

Critically ill patients frequently experience acute pain, which can have multiple causes in the intensive care unit (ICU) setting including surgical and posttraumatic wounds, the use of invasive monitoring devices and mechanical ventilators, prolonged immobilization, and routine nursing care (e.g., dressing changes). The experience of pain differs among patients, but the physiologic consequences of inadequately treated pain are relatively predictable and potentially deleterious. Some physiologic responses to acute pain and stress are mediated by neuroendocrine activation and increased sympathetic tone. Patients may develop tachycardia, increased myocardial oxygen consumption, immunosuppression, hypercoagulability, persistent catabolism, and numerous other metabolic alterations.¹ Additional morbidity may be incurred by pain-related functional limitations such as impaired pulmonary mechanics or delayed ambulation.

ACUTE PAIN ASSESSMENT

The assessment of acute pain in the ICU can be challenging. Unfortunately, many ICU patients cannot provide full or even partial information regarding their pain. However, the inability of ventilated, sedated ICU patients to report pain should not preclude its assessment and management. A number of scales and assessment tools for the evaluation of pain in ICU patients have been developed, such as the visual analog scale, the numeric rating scale, behavioral pain scale, and critical care pain observation scale (Fig. 3-1). In heavily sedated or paralyzed patients, caregivers must use signs of heightened sympathetic activity like hypertension, tachycardia, lacrimation, diaphoresis, and restlessness as surrogate indicators for the presence of pain. Favorable trends in these signs following analgesic administration provide a measure of the success of a given intervention.

OPTIONS FOR ACUTE PAIN THERAPY

Acute pain is triggered by stimulation of peripheral nociceptors in the skin or deeper structures and is a complex process involving multiple mediators at various levels of the neuraxis (Fig. 3-2). Different parts of the pain pathway can be targeted either individually or as part of a comprehensive “multimodal” strategy aimed at multiple sites for additive or synergistic effects. Thus, nociception can be influenced peripherally by the use of nonsteroidal antiinflammatory drugs (NSAIDs) and nerve blocks, at the spinal cord level by the use of epidural or intrathecal medications, and centrally by the use of systemic medications.

Nonsteroidal Antiinflammatory Drugs

Drugs in this class inhibit cyclooxygenase (COX) enzymes, which are involved in synthesis of prostaglandins and related inflammatory mediators in response to injury. COX-1 is a constitutive enzyme that is present in most tissues and, through the production of prostaglandins E₂ and I₂, serves homeostatic and protective functions. COX-2 is an inducible enzyme that is expressed in response to inflammation. As a class, NSAIDs can cause adverse effects that include gastrointestinal (GI) ulceration and GI bleeding, inhibition of platelet function, renal

injury, and bronchospasm in aspirin-sensitive patients (triad of asthma, nasal polypsis, and aspirin allergy).

Ketorolac is one of only two parenteral NSAIDs available in the United States. Although it has been shown to reduce postoperative opioid requirements, prolonged use may be associated with a significant incidence of the aforementioned side effects, primarily GI bleeding and renal injury. Consequently, it is recommended that ketorolac therapy be limited to a maximum of 5 days. In addition, ketorolac, as with all NSAIDs, should be used at decreased dosages or avoided altogether in patients at higher risk of such complications (e.g., advanced age, hypovolemia, or preexisting renal insufficiency).

Intravenous ibuprofen (Caldolor) has recently been approved by the Food and Drug Administration (FDA) as the only other parenteral NSAID for the treatment of pain. It has been demonstrated in several studies to be a safe and well-tolerated adjunctive agent in a multimodal approach of pain management, reducing opioid requirements and decreasing the incidence of opioid-related side effects.²⁻⁴ As with other nonselective NSAIDs, there is risk of GI bleeding and renal injury.

Due to the concern for an increased risk of cardiovascular thrombotic complications, myocardial infarction, and stroke demonstrated with COX-2 selective NSAIDs, there is a Black Box Warning contraindicating the use of both intravenous ibuprofen and ketorolac in perioperative coronary artery bypass graft (CABG) patients. In addition, their use is contraindicated in patients with active or recent GI bleeding or perforation. Unfortunately, the unfavorable adverse effect profile of these agents limits their use in the ICU setting.

Acetaminophen is a para-aminophenol derivative with analgesic and antipyretic properties similar to those of aspirin. The mechanism of action of acetaminophen is still poorly defined. Recent evidence has suggested that it may selectively act as an inhibitor of prostaglandin synthesis in the central nervous system (CNS) rather than in the periphery. When combined with opioids, acetaminophen may be a useful adjunct in pain relief, especially as an alternative to NSAIDs in high-risk patients because of the lower incidence of adverse effects.

An intravenous (IV) form of acetaminophen was approved in 2010 for the management of fever and mild to severe pain. Studies have proven it to be safe and effective in the reduction of pain, leading to decreased opioid requirements and fewer opioid-related side effects.⁴⁻⁷ Compared head-to-head in the setting of acute pain, IV acetaminophen has been shown to be equal and in some cases even more effective than IV morphine.⁸⁻¹⁰ The increased analgesic effects of IV, compared to oral acetaminophen, likely has to do with more favorable pharmacokinetics and avoidance of the hepatic first pass effect. When compared with oral or rectal acetaminophen in equal doses, intravenous administration results in a more rapid elevation in plasma concentrations and higher peak levels of acetaminophen.¹⁰ In fact, the mean peak concentration after infusion of IV acetaminophen is 70% higher than that seen with an equivalent oral dose.¹⁰ These higher plasma concentrations result in a more rapid and significant diffusion across the blood-brain barrier, as demonstrated by significant differences in the peak and total amount of acetaminophen in the cerebrospinal fluid with intravenous versus oral administration.¹¹ Although there are concerns about the use of acetaminophen in patients with liver disease, it has proven to be safe even in this population, although

FIGURE 3-1 ■ Visual analog scale. Pain can be rated between 0 (no pain) and 10 (extreme pain). Use of a graphic such as this allows an intubated patient to indicate his or her level of discomfort by pointing. Other scales use cartoon faces that are either smiling or frowning. (From Higgins TL, Jodka PG, Farid A. Pharmacologic approaches to sedation, pain relief and neuromuscular blockade in the intensive care unit. Part II. Clin Intensive Care. 2003;14[3-4]:91-98.)

FIGURE 3-2 ■ “Map” of the path of nociceptive information from periphery to central nervous system. Modification of information can occur at any point of information transfer. GABA, gamma-aminobutyric acid; TENS, transcutaneous electrical nerve stimulation. (From Kehlet H. Modification of responses to surgery by neural blockade: clinical implications. In: Cousins MJ, Bridenbaugh PO, editors. Neural blockade in clinical anesthesia and pain management. 2nd ed. Philadelphia: Lippincott; 1988:145.)

a reduction of the daily dosage limit is recommended by the manufacturer in cases of mild to moderate hepatic impairment.¹² Its use is contraindicated, however, in cases of severe hepatic impairment.

Opioid Analgesics

This drug class remains the mainstay of ICU analgesia. Although a number of parenteral opioids are available, morphine, hydromorphone, and fentanyl are most commonly used, often as infusions in intubated patients along with a sedative agent. Opioids bind to a variable degree with opioid receptor subtypes (μ , δ , κ) located in the brain, spinal cord, and peripheral sites and modulate the transmission and processing of nociceptive signals. The clinical and pharmacologic properties of opioids depend on several variables, including chemical and solubility properties, dosing regimen, patient characteristics (e.g., age, tolerance, hepatic or renal dysfunction), and presence of active metabolites.

FIGURE 3-3 ■ Pharmacokinetics. A lipophilic drug (drug A) may have a rapid onset and an initially quick distribution, but a prolonged beta-elimination (metabolism) phase resulting in respiratory depression with repeated doses or constant infusion. A less lipophilic drug (drug B) may take longer to redistribute, giving the impression of a prolonged initial duration of action, but it does not accumulate owing to a shorter elimination half-life. Fentanyl is like drug A, whereas morphine is similar to drug B. (From Higgins TL, Jodka PG, Farid A. Pharmacologic approaches to sedation, pain relief and neuromuscular blockade in the intensive care unit. Part II. Clin Intensive Care 2003;14[3-4]:91-98.)

Opioids are excellent analgesics, but they are not amnestic agents. As a class they may suppress respiratory drive and promote sedation, GI symptoms (ileus, nausea and vomiting, constipation), urinary retention, pruritus, or hypotension as a result of the ablation of pain-mediated sympathetic stimulation. In actual practice, however, opioids are relatively neutral in their hemodynamic effects, so long as they are used judiciously in euvolemic patients. Of note, morphine additionally causes hypotension by triggering the release of histamine. This side effect, along with its hepatic metabolism to an active compound, morphine-6-glucuronide, which can accumulate in patients with renal insufficiency, are the main disadvantages of morphine when compared with other parenteral opioids.

Opioids are most commonly administered intravenously in critically ill patients and titrated to effect, either on a scheduled, intermittent basis or as a continuous infusion. This strategy avoids concerns regarding unpredictable bioavailability associated with intramuscular, enteral, or transdermal administration and favors more stable analgesic drug concentrations. The benefits of administering analgesics in this fashion, however, must be balanced against the possibility of unintentional overdosing resulting in excessive sedation, respiratory depression, and in turn, prolonged intubation. To avoid this problem, scheduled daily interruptions of sedative and analgesic drug infusions, often referred to as “sedation vacations” or “sedation holidays,” are recommended as they have been shown to result in shorter durations of mechanical ventilation and ICU stays.¹³ Drugs that are often thought of as short acting, like fentanyl, actually have a markedly prolonged duration of action if given as an infusion, even in patients without significant renal or hepatic dysfunction due to its accumulation in fat (Fig. 3-3). This concept is referred to as the “context-sensitive half-life,” which is defined as the time it takes for the plasma concentration of a drug to decrease by one-half following cessation of a continuous infusion.

Remifentanyl is a potent synthetic opioid with a rapid onset and short duration of action, owing to its unique organ-independent

metabolism and the absence of active metabolites or drug accumulation, even following prolonged infusion. Unlike other opioids that rely heavily on hepatic metabolism, remifentanyl is rapidly hydrolyzed within a matter of minutes by nonspecific plasma and tissue esterases (not plasma cholinesterase or pseudocholinesterase notably, meaning that patients with atypical cholinesterase do not experience a prolonged duration of action). This rapid hydrolysis also prevents drug accumulation during continuous administration. Furthermore, although its major metabolite is renally eliminated, it is virtually devoid of opioid activity, resulting in a stable pharmacokinetic profile even in the presence of severe renal impairment. All of these qualities result in a drug with an extremely short context-sensitive half-life, irrespective of infusion duration. Although this may be particularly useful in critically ill patients who often have comorbid hepatorenal dysfunction and who require prolonged opioid infusions, there are a couple of drawbacks to this drug that limit its widespread use in the ICU setting: First, its potent nature often leads to dose-dependent hypotension and bradycardia if not carefully titrated. Second, its ultra-short duration of action of several minutes can result in abrupt recurrence of pain after an infusion is stopped, which may result in unwanted acute sympathetic stimulation. This may be particularly pronounced in those with a large pain burden, such as postoperative or trauma patients. Other adverse effects of remifentanyl are similar to those of other opioids. Of these, chest wall rigidity resulting in the inability to ventilate is arguably the most worrisome and deserves a brief mention. Although a possible adverse effect of any IV opioid, it may be slightly more common with remifentanyl, particularly when it is given as a bolus or infused at higher rates. This can be treated by administering a neuromuscular blocking agent and reducing or discontinuing the infusion.¹⁴⁻¹⁶

Ketamine

Ketamine is a well-known general anesthetic and analgesic. With the discovery of the *N*-methyl-D-aspartate (NMDA) receptor and its links to nociceptive pain transmission and central sensitization, there has been renewed interest in utilizing ketamine as a potential antihyperalgesic agent. Ketamine is a noncompetitive NMDA receptor antagonist. Although high doses (>2 mg/kg) of ketamine have been implicated in causing psychomimetic effects (excessive sedation, cognitive dysfunction, hallucinations, nightmares), subanesthetic or low doses (<1 mg/kg) of ketamine have demonstrated significant analgesic efficacy without these side effects. Furthermore, there is no evidence to indicate that low doses of ketamine exert any adverse pharmacologic effects related to respiration or cardiovascular function. Low doses of ketamine have not been associated with development of nausea, vomiting, urinary retention, or impaired intestinal motility. Ketamine, in combination with IV opioids, has been shown not only to reduce postoperative opioid consumption but also to improve analgesia.^{5,17}

Methadone

The use of methadone in the outpatient setting in treating opioid addiction and providing relief in chronic pain and palliative care is well established.¹⁸ Its long duration of action (up to 8 hours) compared to other opioids and its dual effects on both opioid and NMDA receptors make it an ideal agent in these settings. In addition to these features, methadone differs pharmacologically from other opioids in several important ways. Its elimination half-life, which is considerably longer than its duration of action, varies dramatically among individuals from 8 to 90 hours, due largely to its highly lipophilic properties leading to drug accumulation.¹⁸ This results in three important considerations regarding drug titration and side effects: First, dosage increases should only be made once every several days, since steady-state plasma concentrations, and therefore full analgesic effects, are not attained until 3 to 5 days after initiation. Second, peak respiratory depressant effects usually occur later and last longer than the peak

analgesic effect, especially during the drug initiation phase. Third, when attempting to discontinue the drug after long-term use the dose should be gradually tapered off, as abrupt discontinuation can lead to withdrawal symptoms. These factors should be kept in mind when dosage adjustments are being made. The delayed respiratory depressant effect is due to drug accumulation rather than the presence of active metabolites as with morphine, since methadone is hepatically metabolized to inactive metabolites. Other than respiratory depression, the most commonly seen serious adverse effect is QT prolongation, which makes regular monitoring of the EKG necessary especially during initiation of therapy, dosage increases, or addition of other medications with QT prolonging effects. Although traditionally used for chronic pain and addiction, there is recent interest in the use of this drug acutely in the inpatient setting in patients who are displaying signs of either opioid tolerance or opioid-induced hyperalgesia.

OPIOID TOLERANCE AND OPIOID-INDUCED HYPERALGESIA

Although at first glance their presentation is quite similar, it is clinically important to distinguish these two situations in terms of the differences in their treatment. Both may result from high-dose opioid consumption and present with uncontrolled pain despite increasing opioid doses. The difference, however, is that patients with opioid-induced hyperalgesia display signs of increasing sensitivity to painful stimuli (hyperalgesia), and the pain is more diffuse (allodynia) and present in an area or distribution that is beyond the initial site. Differentiation of these two scenarios can be difficult, and consultation with a pain management specialist may be necessary.

Opioid tolerance results from repeated exposure to an opioid causing a decreased therapeutic effect through desensitization of antinociceptive mechanisms. Treatment options involve further uptitration of the current opioid regimen, the addition of adjunctive agents with different mechanisms of pain control in a multimodal approach, and attempting an opioid switch or “rotation” to a different opioid analgesic. Although there is debate about the efficacy of the latter approach, methadone in particular has demonstrated particular efficacy when attempting an opioid switch.^{19,20} This is likely due to its dual mechanism of action as an opioid agonist and NMDA receptor antagonist, a quality that is unique among other opioids. Its action at the NMDA receptor not only provides an additional mechanism for pain control but also attenuates hyperalgesia, which arguably also plays a part in many cases of opioid tolerance.^{19,20}

Opioid-induced hyperalgesia, on the other hand, results from repeated exposure to an opioid causing increased pain due to the central sensitization of pronociceptive mechanisms. This has been termed the *wind-up* phenomenon, and presents a challenging problem for the clinician. As its mechanism is different from opioid tolerance, the treatment also differs. Rather than uptitration of opioid agents, attempts should be made to reduce and even discontinue them. This is accomplished through the addition of nonopioid analgesics and through the use of NMDA-receptor antagonists, in particular ketamine. The NMDA receptor is a ligand-gated calcium channel that plays a major role in the development of central sensitization. Through antagonism of this receptor, ketamine has been shown to reverse this phenomenon and effectively treat the hyperalgesia.^{19,20} In addition to its effectiveness in treating opioid-induced hyperalgesia, the use of low-dose ketamine in the treatment of acute pain has been shown to reduce opioid requirements, as previously discussed. This may be particularly beneficial in the postoperative setting.⁵ The opioid-sparing effect of ketamine is partly due to its own intrinsic analgesic effect, but when combined with opioid treatment regimens, it is also likely due to prevention of hyperalgesia.^{17,19} In addition to ketamine, methadone has been shown to improve opioid-induced hyperalgesia, likely in part due to its own action at the NMDA receptor.^{19,20} Initiation of methadone in this setting may also facilitate the tapering and removal of other opioid agents contributing to the hyperalgesia.

Tramadol

Tramadol is a centrally acting synthetic analgesic with two distinct mechanisms of action: It is a weak μ -opioid agonist and a reuptake inhibitor of norepinephrine and, to a lesser extent, serotonin. This results in augmentation of descending inhibitory pathways of pain control. Tramadol has proven to be an effective analgesic, especially when combined with acetaminophen, with fewer opioid-related side effects, most notably gastrointestinal.^{21–24} Tramadol is a racemic mixture of two enantiomers with different pharmacologic effects. One isomer is responsible for the norepinephrine effect and the other the serotonin effect. In addition, its μ -opioid effect is dependent on metabolism by P4502D6 enzyme to an active metabolite. Unfortunately, 5% to 15% of the population are poor metabolizers.²⁵

Tapentadol is a newer agent with a similar dual mechanism of action as a μ -opioid agonist and a norepinephrine uptake inhibitor. Unlike tramadol, it does not require metabolic activation and is a nonracemic molecule, only affecting the reuptake of norepinephrine. These features may increase the efficacy of this agent compared to tramadol. Although tapentadol has 20 times less affinity for the μ -opioid receptor than morphine, it has been demonstrated to have an analgesic effect only three times less than morphine, which is likely explained by its action on norepinephrine.²⁶ When compared with several opioid analgesics including oxycodone in the setting of both acute and chronic pain, tapentadol has shown comparable efficacy with fewer GI adverse effects.^{27–30}

Gabapentin

The gabapentanoids gabapentin and pregabalin are analogs of gamma-aminobutyric acid (GABA). Although initially developed as antiepileptic agents, an indication for which they have not shown great efficacy, these agents have become well established for the long-term treatment of chronic neuropathic pain. Although not completely understood, their mechanism of action involves binding to voltage-gated calcium channels in the central nervous system, downregulating their action and subsequently decreasing neurotransmitter release. This results in inhibition of central sensitization and hyperalgesia, which is responsible for the development of chronic neuropathic pain. Recent studies, however, have investigated the use of these agents as an adjunct to opioid analgesics in the treatment of acute pain, in particular postsurgical pain.

A single preoperative dose of gabapentin has been shown to improve postoperative pain scores and decrease postoperative opioid requirements in a variety of surgical populations.^{31,32} This is theorized to be due to the prevention of surgery-induced central sensitization, which is believed to also play a significant role in acute postoperative pain. There is also evidence that continuation of gabapentanoids in the postoperative period may help to provide increased pain relief and reduce opioid requirements.^{32,33}

Studies using pregabalin in the treatment of acute postoperative pain have demonstrated similar efficacy with this agent.^{5,17,33,34}

Alpha-2 Adrenergic Agonists

In addition to the opiate system, alpha-2 (α_2) adrenergic activation represents another inherent pain-control network in the CNS. The α_2 adrenergic receptor exists in the substantia gelatinosa of the dorsal horn, which is a primary site of action by which this class of drugs can inhibit somatic pain. This receptor system also exists in the brain, where its stimulation can produce sedation. Cardiovascular depression

from α_2 adrenergic agonists can occur at both brain and spinal cord sites. These side effects of sedation and sympathetic inhibition limit α_2 adrenergic agonists to only an adjuvant role as analgesics.

Clonidine was originally used to control blood pressure and heart rate. It binds to α_2 adrenergic and imidazole receptors in the CNS. It has been hypothesized that clonidine acts at α_2 adrenergic receptors in the spinal cord to stimulate acetylcholine release, which acts on both muscarinic and nicotinic receptor subtypes for postoperative pain relief. Clonidine can be administered by oral, IV, or transdermal routes.

A newer centrally acting α_2 agonist is the parenteral agent dexmedetomidine, which possesses a higher affinity for the α_2 receptor than clonidine. Although FDA approved only for sedation, it is being studied as an adjunctive analgesic based on its mechanism and several studies that have demonstrated decreased opioid requirements and improved pain scores with its use.^{35,36}

Neuraxial Analgesic Techniques

The administration of narcotics, local anesthetics, and other agents via intrathecal or epidural catheters targets the processing of pain signals at the level of the spinal cord or nerve root. The use of epidural catheters for regional analgesia in ICU patients may be quite useful, assuming that the pain pattern is regionalized and that there are no contraindications to catheter placement (e.g., coagulopathy, uncontrolled infection, unstable spinal skeletal fractures). In some patients, epidural analgesia may be preferable to IV-administered medications because this approach affords dense regional pain control while largely avoiding the sedative and respiratory side effects of systemic medications. In trauma patients with rib fractures and postsurgical thoracotomy patients, the use of epidural catheters may be particularly helpful in achieving pain control while minimizing respiratory depression in a patient population that is prone to develop respiratory insufficiency and failure due to hypoventilation as a result of uncontrolled pain.

Peripheral Nerve Blocks

Peripheral nerve blocks are an attractive method of providing postoperative analgesia for many orthopedic surgical procedures. The use of peripheral nerve blocks achieved by either a single injection or by continuous infusion via a catheter may provide superior analgesia, reduce opioid consumption, and reduce opioid-related side effects. Unfortunately, this technique is not commonly used in the ICU setting. Due to the aforementioned benefits, however, it should be strongly considered as an alternative to opioids when appropriate.

Multimodal Analgesia

Multimodal analgesia is a concept that was developed as a technique to improve the quality of pain relief while minimizing the adverse effects of opioids. The idea is to use a combination of agents with different mechanisms in an additive and often synergistic effect to achieve adequate analgesia with lower doses of each agent. Utilizing this concept in the ICU can be vitally important, since the adverse effects of drugs are often magnified in the critically ill, especially in the setting of polypharmacy. As we increase our understanding of the etiology of pain, newer agents with different mechanisms of action are being developed, and hopefully one day the concept of treating pain with several agents in a multimodal approach will be common practice in every clinical setting.

ANNOTATED REFERENCES

- Payen JF, Bosson JL, Chanques G, Mantz J, Labarere J; DOLOREA investigators. Pain assessment is associated with decreased duration of mechanical ventilation in the intensive care unit. A post hoc analysis of the DOLOREA Study. *Anesthesiology* 2009;111(6):1308-16.
The author analyzes the recent DOLOREA study out of France and concludes that pain assessment seems to reduce sedative drug dosing, allowing for objective pain evaluation and analgesic drug dosing based on patient report, reducing ventilator days and duration of ICU stay.
- Kumar AB, Brennan TJ. Pain assessment, sedation, and analgesic administration in the intensive care unit. *Anesthesiology* 2009;111(6):1187-8.
This is a prospective, multicenter, observational study of mechanically ventilated patients who received analgesia on day 2 of their ICU stay. Pain assessment in this ICU population was associated with a reduction in the duration of ventilator support and ICU stay. This might be related to higher concomitant rates of sedation assessments and a restricted use of hypnotic drugs when pain was assessed.
- Richman JM, Liu SS, Courpas G, et al. Does continuous peripheral nerve block provide superior pain control to opioids? A meta-analysis. *Anesth Analg* 2006;102(1):248-57.
The authors reviewed 236 articles, all randomized control trials that compared continuous peripheral nerve block (CPNB) analgesia with opioids for the management of postoperative pain. CPNB analgesia, regardless of catheter location, provided superior postoperative analgesia and fewer opioid-related side effects when compared with opioid analgesia.

Fever is defined as an increase in body temperature. Normal body temperature is $36.8^{\circ}\text{C} \pm 0.4^{\circ}\text{C}$. Normally, body temperature varies in a circadian fashion by about 0.6°C , being lowest in the morning and highest in the late afternoon or early evening. A core body temperature of $\geq 38.3^{\circ}\text{C}$ is generally accepted to represent fever.¹ In 2008, a task force from the Society of Critical Care Medicine and the Infectious Disease Society of America concluded that “because fever can have many infectious and noninfectious etiologies, a new fever in a patient in the intensive care unit should trigger a careful clinical assessment rather than automatic orders for laboratory and radiologic tests. A cost-conscious approach to obtaining cultures and imaging studies should be undertaken if indicated after a clinical evaluation.”¹

Fever is a common finding in patients admitted to an intensive care unit (ICU), being present at one time or another in almost 50% of cases. Moreover, fever is an independent risk factor for mortality in patients admitted to ICUs.²

The pathogenesis of fever triggered by infectious agents is complex.^{2,3} Classically, fever was thought to be triggered by the peripheral release of various cytokines—notably, interleukin 1-beta (IL-1 β), tumor necrosis factor (TNF), IL-6, and possibly interferon-alpha (IFN- α)—that are capable of up-regulating the expression of two key enzymes that are involved in the production of prostaglandin E₂ (PGE₂), namely: cyclooxygenase (COX)-2 and microsomal prostaglandin E synthase-1 (mPGES-1). The central role of PGE₂ in the pathogenesis of fever is supported by the following findings: first, febrile responses to lipopolysaccharide (LPS) and other inflammatory stimuli are depressed by drugs that inhibit PG synthesis; second, mice that are genetically deficient in either COX-2 or mPGES-1 do not become febrile after an LPS challenge. Although PGE₂ can be produced by immunostimulated macrophages in the periphery, the PGE₂ that is responsible for fever is probably generated in the central nervous system (CNS). PGE₂ binds to prostaglandin receptors located on a cluster of neurons in the pre-optic region of the hypothalamus. Although there are four subtypes of PGE₂ receptors, only one, PGE₂ receptor 3 (EP3), is required for the development of fever in response to IL-1 β , LPS, or PGE₂.⁴ The activation of EP3 triggers a number of neurohumoral and physiologic changes that lead to increased body temperature. The antipyretic effects of various nonsteroidal antiinflammatory drugs (NSAIDs), such as aspirin and ibuprofen, are due to the inhibition of COX-2-dependent PGE₂ biosynthesis in the CNS. The mechanism by which acetaminophen reduces fever might involve COX-2 inhibition in the CNS, but it remains controversial and poorly understood.⁵⁻⁷

The classical view of the pathogenesis of fever associated with infection has been updated by the proposal that pyrogenic stimuli trigger the activation of vagal afferent signals originating from the liver and travelling to the nucleus tractus solitarius in the brainstem. These signals are subsequently transmitted to the hypothalamus, where an early increase in temperature is mediated in a PGE₂-independent fashion via an α_1 -adrenergic receptor-dependent pathway. A secondary (delayed) increase in temperature is mediated via an α_2 -adrenergic-dependent pathway that leads to an increase in PGE₂ production secondary to the increased expression of COX-2.

Body temperature can be measured using an oral, axillary, or rectal mercury-filled glass thermometer. These traditional approaches, however, have been largely replaced by a variety of safer and more

environmentally friendly methods that use thermistors located on catheters or probes placed in the pulmonary artery, distal esophagus, urinary bladder, or external ear canal. Infrared detectors can be used to measure tympanic membrane temperature. Forehead skin temperature can be measured using a temperature-sensitive patch.

Fever is a cardinal sign of infection. Accordingly, any new onset of fever should trigger a careful diagnostic evaluation for investigating the source of infection. The diagnostic evaluation should be thorough and tailored to the recent history of the patient. For example, the possibility of a CNS infection should receive greater attention in a patient with recent or ongoing CNS instrumentation. By the same token, if a patient recently underwent a gastrointestinal surgical procedure, the clinician should have a high index of suspicion for an intraabdominal source of infection. Key elements in the assessment of new-onset fever in the ICU are listed in [Box 4-1](#). Common sources of infection in ICU patients are listed in [Box 4-2](#).

Although fever in the ICU is most commonly due to infection, myriad noninfectious causes of systemic inflammation ([Box 4-3](#)) can also result in hyperthermia. Some authors claim that noninfectious causes of fever rarely result in a core temperature above 38.9°C ,^{8,9} but rigorous data in support of this view are lacking. Still, infections are rarely if ever associated with core temperatures over 41.1°C . When the core temperature is this high, the clinician should suspect malignant hyperthermia, neuroleptic malignant syndrome, or heat stroke.

On theoretical grounds, the routine treatment of fever would seem to be ill-advised. Hyperthermia is an adaptive response that enhances the host's ability to fight infection.¹⁰ In addition, body temperature becomes an unreliable clinical parameter when patients are receiving antipyretic therapy. Still, currently available data are insufficient to determine whether fever should be routinely treated in ICU patients. In one randomized clinical trial that enrolled 82 surgical ICU patients, the protocolized administration of acetaminophen when body temperature exceeded 38.5°C was compared to the treatment of fever only when temperature exceeded 40°C . More aggressive treatment of fever in this study was associated with a trend toward higher mortality ($P = 0.06$).¹¹ In contrast to these findings, Schortgen et al. randomized febrile patients with septic shock requiring vasopressors, mechanical ventilation, and sedation to either external cooling ($n = 101$) for 48 hours to achieve normothermia (36.5°C to 37°C) or no external cooling ($n = 99$).¹² Day 14 mortality was significantly lower in the group randomized to external cooling ($P = 0.013$). In another study, 120 febrile adults (not all critically ill) were randomized to treatment with intravenous ibuprofen (100, 200, or 400 mg) or placebo every 4 hours for a total of 6 doses. There was no significant difference in the rate of serious adverse events, such as acute kidney injury, bleeding, or mortality, between the groups.¹³

Although it is unclear whether hyperthermia should be routinely treated in ICU patients, antipyretics should be administered to selected patients with fever, notably those with acute coronary syndromes (i.e., myocardial infarction or unstable angina), because the tachycardia that usually accompanies the febrile response can exacerbate imbalances between myocardial oxygen delivery and demand. Febrile patients with head trauma, subarachnoid hemorrhage, or stroke should receive cooling (using antipyretics and/or external cooling devices) to prevent temperature-related increases in cerebral oxygen utilization. Children with temperatures higher than 40°C or with a history of seizures should also be treated.

BOX 4-1**Key Elements in the Evaluation of New-Onset Fever in ICU Patients**

- Be familiar with the patient's history. Pay particular attention to possible predisposing causes of fever.
- Perform a careful physical examination. Pay particular attention to surgical wounds and vascular access sites. Look for evidence of pressure-induced skin ulceration. In patients with recent median sternotomy, evaluate the stability of the chest closure. Perform a careful abdominal examination.
- Obtain or review a recent chest X-ray, looking for evidence of new infiltrates or effusions.
- Obtain appropriate laboratory studies. At a minimum, these studies should include a peripheral white blood cell count and cultures of blood and urine. If the patient is endotracheally intubated or has a tracheotomy, obtain a sample of sputum for Gram stain. In some centers, sputum is routinely cultured. In other centers, bronchoalveolar lavage or bronchial brushing for quantitative microbiology is performed using blind or bronchoscopic methods.
- In patients receiving antibiotics for more than 3 days, a stool sample should be analyzed for the presence of *Clostridium difficile* toxin, unless a high sensitivity assay for the toxin was performed recently and was negative.
- More extensive diagnostic evaluation should be considered in a graded fashion based on history, physical examination findings, laboratory results, persistence of fever despite presumably appropriate antimicrobial chemotherapy, or clinical instability. These additional tests and procedures include diagnostic thoracentesis, paracentesis, and lumbar puncture. Imaging studies should be considered, including abdominal or cardiac ultrasonography and head, chest, or abdominal computed tomography.

Hypothermia blankets are often used to lower the core temperature in febrile ICU patients, although these blankets are no more effective for cooling patients than antipyretic agents.^{14,15} Hypothermia blankets can cause large temperature fluctuations and are associated with rebound hyperthermia when removed. Additionally, external cooling can augment hypermetabolism and actually promote persistent fever. Lenhardt and colleagues demonstrated that active external cooling in volunteers with induced fever increased oxygen consumption by 35% to 40% and was associated with a significant increase in circulating norepinephrine and norepinephrine concentrations.¹⁶

In view of these phenomena, the administration of an antipyretic agent is the recommended approach when the treatment of fever is warranted. Commonly used antipyretics include isoform nonselective COX inhibitors, such as ibuprofen or aspirin, or acetaminophen. Because corticosteroids (hydrocortisone, methylprednisolone) are potent antiinflammatory agents, these drugs can suppress the febrile response to infection. Other antiinflammatory agents have a similar effect, so absence of fever should not be used to rule out infection, especially in patients receiving corticosteroids or other potent antiinflammatory drugs.

A reasonable approach for evaluating fever in ICU patients was described by Marik.⁸ Blood cultures should be obtained whenever an ICU patient develops a new fever. The sensitivity of blood cultures for detecting bacteremia depends to a large extent on the volume of blood inoculated into culture media. Whenever possible, at least 10 to 15 mL of blood should be withdrawn and inoculated into 2 or 3 bottles or tubes at a ratio of 1 mL of blood per 5 mL of medium.¹

A comprehensive physical examination should be carried out, and a chest X-ray obtained and reviewed. Noninfectious causes of fever should be excluded. In patients with an obvious focus of infection, a directed diagnostic evaluation is necessary. However, if there is no obvious source of infection and the patient is not clinically deteriorating, it is reasonable to obtain blood cultures and observe the patient for 48 hours before ordering additional diagnostic studies or starting empirical antibiotics. This approach is not reasonable, however, if new fever is accompanied by other signs of worsening clinical status such as arterial hypotension, oliguria, increasing confusion, rising serum lactate concentration, falling platelet count, or worsening coagulopathy. Nor is this approach reasonable if the core temperature is above

39°C but below 41.1°C. Patients in this category should receive empirical antimicrobial chemotherapy while aggressive attempts are made to diagnose the source of infection. All febrile neutropenic patients should receive broad-spectrum empirical antimicrobial chemotherapy after appropriate cultures are obtained.

Intravascular catheters are commonly suspected as a source of infection and fever in ICU patients and can cause fever due to localized or systemic (bloodstream) infection. In patients with a new onset of fever but without other ominous signs (e.g., hypotension, profound thrombocytopenia, acute respiratory distress syndrome), it is unnecessary to remove all intravascular catheters. In contrast, if one or more of these (or other) ominous signs are present, the most prudent course of action is to remove all vascular access catheters, including tunneled and/or cuffed devices. In many institutions, routine culturing of catheter tips (using semiquantitative methods on solid media) is no longer thought to be cost effective because the results of such studies rarely change the subsequent therapy strategy.^{17,18}

Fever is a common feature of the systemic inflammatory response syndrome (SIRS), irrespective of whether the underlying cause is infectious or noninfectious.¹⁹ Procalcitonin, a precursor of the polypeptide hormone, calcitonin, has been studied extensively as a circulating marker that can be used to differentiate infectious from noninfectious causes of SIRS in ICU or emergency department patients. A recent meta-analysis concluded that "procalcitonin represents a good biological diagnostic marker for sepsis, severe sepsis, or septic shock."²⁰ Several randomized controlled trials have investigated the feasibility of using the results of procalcitonin assays for making decisions regarding starting or stopping antibiotics for patients with proven or suspected

respiratory infections. According to a recent meta-analysis of these studies, the "use of procalcitonin to guide the initiation and duration of antibiotic treatment was not associated with higher mortality rates or treatment failure, [and] antibiotic consumption was significantly reduced."²¹ Thus, measurements of procalcitonin can be a useful adjunct for the evaluation of fever in ICU patients, but this assay is not a replacement for other key diagnostic modalities: careful physical examination, chest X-ray, assessment of sputum Gram stain findings, and appropriate cultures of blood, urine, sputum, or bronchoalveolar lavage fluid.

An acute elevation in systemic blood pressure is termed a *hypertensive crisis*, a clinical condition that includes both *hypertensive urgency* (HU) and *hypertensive emergency* (HE). HE is characterized by a severe elevation in systemic blood pressure combined with new or progressive end-organ damage most frequently in the cardiac, renal, and/or central nervous system.¹ HE is an infrequent clinical presentation of acute hypertension that requires immediate, titrated, blood pressure reduction. Although HE is typically associated with a blood pressure elevation > 180/110 mm Hg, the diagnosis of HE is based upon the patient's clinical signs and symptoms rather than a specific blood pressure level. Clinical conditions associated with HE might include hypertensive encephalopathy, intracranial hemorrhage, acute coronary syndrome, acute pulmonary edema, aortic dissection, acute renal failure, and eclampsia.

In contrast, HU is characterized by a critically elevated blood pressure (>180/110 mm Hg) without evidence for acute and progressive dysfunction of target organs. In HU, a more gradual reduction of blood pressure over several hours to days is the therapeutic target. A rapid reduction in blood pressure in HU has no proven benefit, and cerebral or myocardial ischemia can be induced by aggressive antihypertensive therapy if the blood pressure falls below a level needed to maintain adequate tissue perfusion. HU is not to be ignored, however, as it can progress to end-organ damage if blood pressure remains uncontrolled over a sustained interval.

In the current treatment era for HE, a 25-institution U.S. analysis reported a hospital mortality rate of 6.9% with an aggregate 90-day mortality rate of 11% and a 90-day readmission rate of 37%.² While the frequency of hospitalization for hypertensive emergency may be increasing, the all-cause hospital mortality for these patients continues to decrease.

■ PATHOPHYSIOLOGY

An acute elevation in systemic arterial blood pressure (BP) most fundamentally involves an increase in systemic vascular resistance. This increase in vascular resistance is attributed to a complex interaction of vascular mediators with a triggering factor in the setting of preexisting hypertension. Vasoconstriction can be promoted by circulating catecholamines, angiotensin II (ATII), vasopressin, thromboxane (TxA₂), and/or endothelin-1 (ET1). In contrast, compensatory production of local counterregulatory vasodilators including nitric oxide (NO) and prostacyclin (PGI₂) is inadequate to maintain homeostatic balance. The early stages of HE are associated with a naturesis that further stimulates the release of vasoconstrictor substances from the kidney.

Specific cellular mechanisms of vascular injury in HE appear to involve proinflammatory responses incorporating cytokine secretion, monocyte activation, and upregulation of endothelial adhesion molecules.³ These proinflammatory factors extend the endothelial injury by promoting endothelial permeability and activating the coagulation cascade.

This cascade of intravascular events leads to the characteristic pathologic findings of obliterative vascular lesions. The vascular changes, evident to the clinician during examination of the retina, are mirrored by similar changes in the kidney, leading to a proliferative arteritis and, in advanced stages of the process, fibrinoid necrosis. A state of relative ischemia results in the affected organs, leading to end-organ dysfunction. The thrombotic microangiopathy (TMA) that characterizes the advanced stages of HE is a prothrombotic state characterized

by endothelial dysfunction, platelet activation, and thrombin generation, with enhanced fibrinolytic activity.³

The potential adverse effects of aggressive blood pressure control have been most carefully studied in the cerebral circulation. Cerebrovascular arteriolar tone is adjusted over a range of cerebral perfusion pressures (CPP) to maintain a constant cerebral blood flow (CBF). Increases in CPP promote an increase in vascular resistance, whereas decreases in CPP act to vasodilate the cerebral vasculature. Constant flow is therefore maintained over a range of mean arterial pressure (MAP) from approximately 60 mm Hg to 150 mm Hg.⁴ As MAP increases to values >180 mm Hg or above the upper limit of autoregulation, cerebral hyperperfusion can occur, resulting in cerebral edema. Conversely, when CPP falls below the lower limit of autoregulation, CBF decreases, and tissue ischemia may occur. In patients with longstanding hypertension, a rightward shift of the CPP-CBF relationship occurs such that the lower limit of autoregulation occurs at a value higher than that in normal subjects. Comparative studies in hypertensive and normotensive patients suggest that the lower limit of autoregulation is about 20% below the resting MAP for both, although the absolute value is higher for the hypertensive patient. These data support the common recommendation that a safe level of blood pressure reduction in the HE setting is a 10% to 20% reduction of MAP from the highest values on clinical presentation, or a diastolic blood pressure typically in the 100- to 110-mm Hg range.

■ CLINICAL PRESENTATION

According to the STAT registry, the most common presenting symptoms in HE include shortness of breath (29%), chest pain (26%), headache (23%), altered mental status (20%), and a focal neurologic deficit (11%).² The most common admitting diagnoses are severe hypertension (27%), subarachnoid hemorrhage (11%), acute coronary syndrome (10%), and heart failure (8%). In approximately 25% of patients with HE, there is a history of either chronic or current medication nonadherence, and 11% of patients are current drug abusers. No specific blood pressure level defines HE, but the mean systolic blood pressure in the STAT registry was 200 mm Hg (IQR, 186-220), and the median diastolic blood pressure (DBP) was 110 mm Hg (IQR, 93-123).²

A detailed history is indicated, with some attention to the use of prescription medications associated with hypertension. Hypertensive emergencies may also develop as secondary hypertension in association with such diverse etiologies as renal vascular disease, sleep apnea, hyperaldosteronism, pheochromocytoma, and pregnancy (preeclampsia). In addition, illicit drug use is a major risk factor for the development of hypertensive emergencies.

Blood pressure should be measured in both arms using an appropriately sized cuff. Repeated blood pressure measures are indicated, as a significant fraction of patients will resolve hypertension with bed rest and initial observation. Physical examination including a fundoscopic examination should focus on identification of signs suggesting end-organ dysfunction.

Hypertension and Cerebrovascular Disease Hypertensive Encephalopathy

Acute elevations in systemic arterial blood pressure can lead to hypertensive encephalopathy (HEN). The clinical manifestations include headache, confusion or a depressed level of consciousness, nausea and

vomiting, visual disturbances, or seizures (generalized or focal). Patients may present with focal neurologic deficits, although this finding is more common in cerebrovascular accidents. Rarely, HEN can present with brainstem involvement manifesting as ataxia and/or diplopia.⁵ If left untreated, the condition can progress to coma and death. Retinal findings, including arteriolar spasm, exudates or hemorrhages, and papilledema may be present but are not a requirement. MRI studies show edema involving the subcortical white matter of the parieto-occipital regions best seen on T2 and FLAIR imaging, a finding termed *posterior leukoencephalopathy*. Approximately two-thirds of patients will also have hyperintense lesions on T2 and FLAIR imaging in the frontal and temporal lobes, and one-third will have brainstem, cerebellum, or basal ganglia involvement.⁶ The imaging findings are typically bilateral but can be asymmetric. HEN is the most common cause of posterior reversible encephalopathy syndrome (PRES).⁶ An improvement or resolution of the radiographic findings is delayed often in comparison to clinical improvement. Seizures can occur in patients with PRES and may include both focal and generalized features.⁷

The diagnosis of HEN is confirmed by the absence of other conditions and the prompt resolution of symptoms and neuroimaging abnormalities with effective blood pressure control. The failure of a patient to improve within 6 to 12 hours of blood pressure reduction should suggest an alternative cause of the encephalopathy. The condition is typically reversible with no observable adverse outcomes.

Acute Stroke

The majority of patients with acute stroke have an elevated systolic blood pressure on presentation to the hospital that often declines to normal within 48 hours of presentation. Current data are contradictory whether hypertension in the early phase of acute stroke contributes to a worse patient outcome or is a surrogate marker of stroke severity.

During acute stroke, cerebral autoregulation may be compromised in ischemic tissue, and lowering of blood pressure may further compromise cerebral blood flow and extend ischemic injury. Medications used to treat hypertension may lead to cerebral vasodilation, augmenting cerebral blood flow and leading to progression in cerebral edema. Ideally, a "correct" level of MAP should be maintained in each patient to maintain cerebral perfusion pressure without worsening cerebral edema or progression of the lesion, but the clinical determination of this ideal value is often difficult.

Consensus guidelines recommend that blood pressure not be treated acutely in the patient with ischemic stroke unless the hypertension is extreme (systolic blood pressure >220 mmHg or diastolic blood pressure >120 mm Hg) or the patient has active end-organ dysfunction in other organ systems.⁸ When treatment is indicated, cautious lowering of blood pressure by approximately 15 percent during the first 24 hours after stroke onset is suggested. Antihypertensive medications can be restarted at approximately 24 hours after stroke onset in patients with preexisting hypertension who are neurologically stable, unless a specific contraindication to restarting treatment exists. Special considerations are patients with extracranial or intracranial stenosis and candidates for thrombolytic therapy. The former group may be critically dependent on perfusion pressure, so blood pressure therapy may be further delayed. In contrast, treatment is recommended before lytic therapy is started, so that systolic blood pressure is ≤ 185 mm Hg and diastolic blood pressure is ≤ 110 mm Hg before lytic therapy administration.⁸ The blood pressure should be stabilized and maintained below 180/105 mm Hg for at least 24 hours after intravenous lytic therapy.

Blood pressure is frequently elevated in patients with acute intracranial hemorrhage (IH), often to a greater degree than seen in ischemic stroke. Theoretically, severe elevations in blood pressure may worsen IH by creating a continued force for bleeding. However, the increased arterial pressure may also be necessary to maintain cerebral perfusion in this setting, and aggressive blood pressure management could lead to worsening cerebral ischemia. For patients with suspected elevated intracranial pressure (ICP), ICP monitoring may be indicated to help maintain cerebral perfusion pressure during therapeutic interventions. American Heart Association guidelines, admittedly arbitrary

and not evidenced based, suggest a target MAP of less than 110 mm Hg or a blood pressure of less than 160/90 mm Hg while maintaining a reasonable cerebral perfusion pressure in patients with suspected elevated ICP.⁹ Based upon the results of INTERACT 1 and 2, which showed a decreasing trend in the primary outcome of death or severe disability, significant improvements in secondary functional outcomes, and reassuring safety data, many investigators advocate acute blood pressure reduction to a target systolic blood pressure of 140 mm Hg for patients with spontaneous IH.¹⁰

Hypertension and Cardiovascular Disease

Acute Coronary Syndrome

Patients presenting with acute myocardial ischemia and/or infarction frequently suffer from elevated MAP. The increased afterload raises the myocardial oxygen demand. Decreasing the heart rate and blood pressure in these patients will favorably decrease the myocardial oxygen demand and infarct size. However, a reduction in arterial pressure in this setting should be done cautiously. Potent systemic vasodilation without coronary vasodilation can lead to a decrease in coronary artery perfusion pressure and infarct extension. For this reason, nitroglycerin, a potent coronary vasodilator, is often the antihypertensive agent of choice in acute coronary syndromes. In combination with beta-blocker therapy, this approach can reduce cardiac workload significantly in the setting of ischemia.

Acute Left Ventricular Dysfunction

Hypertension in acute left ventricular dysfunction (LVD) may be the inciting event with secondary myocardial dysfunction, or alternatively a secondary component of acute pulmonary edema due to the sympathoadrenal response to hypoxemia, increased work of breathing, and anxiety. Regardless, efforts to control hypertension in LVD are essential to resolve increased myocardial workload and diastolic dysfunction. However, the use of vasodilators in patients with LVD and normal to low blood pressure can lead to hemodynamic instability, impaired organ perfusion, and, potentially, shock.

Intravenous vasodilators, including nitroglycerin and calcium channel antagonists, which permit rapid titration of blood pressure, are generally preferred in the setting of acute LVD. The dihydropyridine calcium antagonists nifedipine and clevidipine have been associated with reduced systemic arterial pressure with preservation of coronary blood flow. Patients with LVD may be initially hypertensive secondary to high initial catecholamine levels. With effective treatment or control of hypoxemia and anxiety, blood pressure may fall rapidly, especially in the setting of concomitant diuresis. Thus, longer-acting medications such as ACE inhibitors or ARB therapy are avoided early in the treatment period.

Patients with HE in particular may have suffered a natriuresis resulting in elevated levels of renin production by the kidney and, hence, increased circulating levels of the potent endogenous vasoconstrictor angiotensin II. Further reductions in intravascular volume and renal perfusion can lead to further increases in circulating angiotensin II levels. Therefore, aggressive diuresis before blood pressure control is not advised. Medications that increase cardiac work (e.g., hydralazine) or impair cardiac contractility (e.g., labetalol) are contraindicated as primary therapy for hypertension in the setting of LVD.

Acute Aortic Dissection

Aortic dissection results from an intimal tear in the aortic wall. The primary morbidity and mortality result from extension of that tear. Extension is promoted by factors that increase the rate of change of aortic pressure (dp/dt), including elevation in blood pressure, heart rate, and myocardial stroke volume. A high clinical suspicion is required, as the classic triad of chest pain, arm-leg BP differential, and a widened mediastinum is present in only one-quarter of cases.

Blood pressure in aortic dissection should be promptly reduced to near-normal levels. Combined modality therapy to promote vasodilation (nifedipine) and control cardiac contractility (beta-blocker) is

advocated for this disorder, with initial aggressive control of the heart rate (~60 beats per min). Isolated treatment with a vasodilator alone could precipitate a reflex tachycardia, increasing dp/dt.

Hypertension and Renovascular Disease

The kidney is both a source of mediators that promote hypertension (i.e., angiotensin II) and a target of high systemic arterial pressure. Chronic hypertension is second to diabetes mellitus as a primary cause of renal insufficiency. Elevated systemic arterial pressure should be regulated in patients with underlying renal insufficiency and a comprehensive workup initiated to determine the cause and effect relationship. Traditional vasodilator medications are preferred to ACE inhibitors in the acute setting because ACE inhibitors can compromise renal function.

Scleroderma Renal Crisis

Scleroderma renal crisis (SRC) is characterized by acute renal failure associated with moderate to severe hypertension and a normal to minimally abnormal urine sediment. Significant risk factors for SRC are the presence of diffuse scleroderma skin involvement and recent treatment with high-dose corticosteroids.¹¹ SRC results in marked activation of the renin-angiotensin system. Aggressive control of blood pressure using ACE inhibitors, particularly early in the disease process, controls blood pressure in up to 90% of patients and promotes recovery in renal function.¹¹

Hypertension in Excess Catecholamine States

Pheochromocytoma

Pheochromocytoma results in the production of circulating catecholamines, which causes hypertension, diaphoresis, tachycardia, and paresthesias of the hands and feet. These attacks can last from minutes to days and occur as frequently as several times a day or as infrequently as once per month. Operative manipulation of the tumor can result in perioperative hypertension. Hypertension therapy in this disorder must avoid the use of isolated therapy with a beta-blocker, a strategy that can lead to unopposed alpha-adrenergic stimulation with the risk of further vasoconstriction and blood pressure elevation. The preferred agents for treatment of hypertension due to pheochromocytoma are nitroprusside, nicardipine, and phentolamine, a potent alpha-adrenergic antagonist. If necessary, phentolamine can be combined with a beta-blocker or a combined alpha/beta-blocker such as labetalol, which can be used safely.

Pharmacologically Mediated Hypertension

The administration of exogenous substances (medications or illicit drugs) and/or abrupt withdrawal of substances can be associated with a hypertensive crisis. Rapid withdrawal or tapering of clonidine has been associated with a hyperadrenergic state characterized by hypertension, diaphoresis, headache, and anxiety. The syndrome is best treated by restarting the clonidine. If the symptoms are extreme, treatment is similar to that for the patient with pheochromocytoma. Hypertension can also occur during the withdrawal phase of alcohol abuse.

Monoamine oxidase (MAO) inhibitors can be associated with hypertension if the patient consumes foods or medications containing tyramine or other sympathomimetic amines. MAO inhibitors interfere with the degradation of tyramine in the intestine, leading to excess absorption and tyramine-induced catecholamine activity in the circulation.

Medications including metoclopramide, calcineurin inhibitors, cyclosporine, tacrolimus, and drugs of abuse, such as cocaine, phenylpropanolamine, phencyclidine, and methamphetamine must all be considered as possible factors in the intensive care patient with elevated systemic arterial pressure.

Hypertensive states may occur following spinal cord injury, particularly with stimulation of dermatomes and muscles below the level

of the injury. The blood pressure elevation is believed to result from excess stimulation of sympathetic neurons. The hypertension is accompanied by bradycardia through stimulation of the baroreceptor reflex. Treatment is focused on minimizing stimulation and providing medical therapy as necessary. Patients with Guillain-Barré can manifest a similar syndrome.

Hypertension and Miscellaneous Conditions

Preeclampsia/Eclampsia

Hypertension can occur in pregnant women or women in the postpartum period. Acute severe hypertension in the second half of gestation may occur in preeclampsia, gestational hypertension, or HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome. Hypertension occurs as one manifestation of preeclampsia in the pregnant patient; the other key features are proteinuria and edema. Severe hypertension, particularly systolic hypertension in pregnancy, can be associated with central nervous system injury including cerebral infarction and hemorrhage.

The optimal treatment of preeclampsia is delivery of the fetus, an approach that prevents progression to eclampsia. However, blood pressure should be regulated to prevent end-organ damage. The treatment goal is to achieve a range of 140-150/90-100 mm Hg.¹² Intravenous (IV) labetalol and hydralazine have been considered the first-line medications for the management of severe hypertension in pregnant and postpartum women, although more recent guidelines have included nifedipine.¹² Magnesium sulfate is not considered an antihypertensive agent but rather is administered for seizure prophylaxis in severe preeclampsia and eclampsia. Sodium nitroprusside (fetal defects), ACE inhibitors (renal dysfunction in fetus), and trimethaphan (meconium ileus) should be avoided.

Postoperative Hypertension

Postoperative hypertension most often occurs following vascular surgery procedures in patients with a background history of hypertension. The duration of postoperative hypertensive crisis is often brief (2-6 hours) but has been linked to postoperative cardiac and renal complications including bleeding from suture lines, intracerebral hemorrhage, stroke, and left ventricular dysfunction.¹³

Factors such as pain, anxiety, hypervolemia, hypoxemia, hypercarbia, and nausea are reversible factors that can contribute to postoperative hypertension and should be addressed. Postoperative hypertension is often limited in duration (2 to 12 hours), and aggressive attempts to lower blood pressure acutely can lead to delayed hypotension.

■ ANTIHYPERTENSIVE MEDICATIONS

A summary of the medications available for the treatment of elevated systemic arterial pressure is outlined in Table 5-1. Currently, the clinician has very limited comparative data to guide initial therapy for the patient with hypertension. Patients without end-organ dysfunction (HU) are best treated with oral agents, allowing a gradual reduction in blood pressure over 24 to 48 hours. In contrast, for patients with hypertensive emergency (HE), short-acting titratable medications provided in a monitored environment are preferred, as hypotension and compromised organ perfusion must be avoided. The sublingual and intramuscular routes should be avoided due to unpredictable pharmacokinetics. The conversion to oral therapy is timed to stable BP readings and no further progression in end-organ dysfunction.

Patients receiving nicardipine were more likely to have their BP controlled to prospectively defined target ranges at 30 min compared to those receiving labetalol in one of the few comparative effectiveness trials of nicardipine versus IV labetalol in the ED management of acute hypertension.¹⁴

Clevidipine was compared to three commonly employed medications for the treatment of postoperative hypertension (nitroglycerin (NTG), sodium nitroprusside (SNP), and nicardipine (NIC)).¹⁵ The

TABLE 5-1 Intravenous Antihypertensive Therapy

| MEDICATION (ROUTE) | PHARMACOLOGY | DOSING | INDICATION | CONTRAINDICATION |
|----------------------------------|--------------------------------------|---|--|---|
| NITRIC OXIDE VASODILATORS | | | | |
| Nitroprusside (IV infusion) | Onset: 2-3 min Duration: 2-3 min | Init: 0.25 to 0.5 mcg/kg/min Max: 2 mcg/kg/min | Most hypertensive emergencies | Contraindication in pregnancy. Caution with use in the settings of cerebral edema, acute coronary syndrome, or azotemia |
| Nitroglycerin (IV infusion) | Onset: 2-5 min Duration: 5-10 min | Init: 5 mcg/min Max: 200 mcg/min | Acute coronary syndromes | Contraindication in pregnancy. Caution with use in a volume-contracted patient |
| CALCIUM CHANNEL BLOCKERS | | | | |
| Nicardipine (IV infusion) | Onset: 5-15 min Duration: 4-6 h | Init: 5 mg/h Max: 15 mg/h | Most hypertensive emergencies | |
| Clevidipine (IV infusion) | Onset: 2-4 min Duration: 5-15 min | Init: 1-2 mg/h Max: 32 mg/h | Most hypertensive emergencies | Contraindicated with allergy to soybean or egg products. Contraindicated with defective lipid metabolism |
| MISCELLANEOUS MEDICATIONS | | | | |
| Labetalol (IV infusion, oral) | Onset: 2-5 min Duration: 2-4 h | Init: IV bolus 20 mg Repeat bolus 20-80 mg q 10 min Infusion: 1 to 2 mg/min | Most hypertensive emergencies | Contraindication in airflow obstruction, acute heart failure, or in patients nontolerant of beta-blockers |
| Phentolamine (IV) | Onset: 1-2 min Duration: 10-30min | Test dose: 1 mg Repeat 5 mg boluses or continuous infusion may be provided. | Pheochromocytoma Catecholamine withdrawal Catecholamine excess | |
| Enalapril | Onset: 15 min Duration: 12-24 h | 1.25-5 mg q 6 h | Scleroderma renal crisis | Caution with use in acute coronary syndrome. Not titratable |
| Hydralazine (IV, oral) | Onset: 10-20 min Duration: 2-4 h | Init: 10 mg q 20 min Max: 20 mg | Pregnancy | |

primary end point was safety as assessed by the incidence of death, stroke, myocardial infarction (MI), and renal dysfunction from the initiation of study drug infusion through postoperative day 30. There was no difference in the CLV-treated patients compared with the other treatment groups. However, mortality was significantly higher for SNP-treated patients compared to CLV-treated patients.

Nitric Oxide Vasodilators

Sodium nitroprusside (SNP) is a potent arterial and venous vasodilator that reduces preload and afterload. SNP was once the gold standard for the treatment of HE due to its short duration of action, allowing careful titration. The blood pressure response to SNP is rapid and mandates its use in a well-monitored environment with frequent blood pressure monitoring. The arteriolar and venous vasodilating activity of SNP may not be uniform, however. Redistribution of oxygenated blood flow from nonresponsive ischemic regions to vasodilated nonischemic coronary arteries can reduce coronary perfusion pressure, resulting in a "coronary steal" syndrome. A similar "cerebral steal" syndrome has been suggested with the use of SNP due to preferential vasodilation in systemic vascular beds versus cerebral vessels. Through dilation of large capacitance vessels, SNP can increase cerebral blood volume, leading to an increase in intracranial pressure that raises additional concerns in patients with increased ICP. SNP is rarely associated with cyanide or thiocyanate toxicity, occurring primarily in patients receiving infusions for greater than 24 to 48 hours, in the setting of underlying renal insufficiency, and/or the use of doses that exceed the capacity of the body to detoxify cyanide (more than 2 µg/kg per min). Despite the marked potency and rapidly titratable characteristics of SNP, the recognized adverse effects on cerebral and coronary blood flow combined with the potential toxicities have made newer alternative agents favored over SNP for the treatment of HE.

Nitroglycerin (NTG) is a coronary vascular dilation and a systemic venodilator that reduces myocardial preload. NTG demonstrates arterial smooth muscle effects only at higher dose infusions. The drug is

contraindicated in patients with significant volume depletion, as vasodilation in these patients will further lower preload, reduce cardiac output, and compromise overall systemic perfusion. When administered by the intravenous route, the medication has a relatively short duration of action. The drug has favorable effects for patients with acute coronary syndromes, including reducing myocardial oxygen demand via its effects on preload and afterload and augmenting myocardial oxygen delivery through its effects on the coronary circulation. Headache is the most common adverse effect of NTG, and methemoglobinemia is a rare complication of prolonged nitroglycerin therapy.

Calcium Channel Blockers

Calcium channel blockers (CCB) are a heterogeneous class of medications used in the treatment of hypertension emergency. Dihydropyridines, a specific class of CCB (e.g., nicardipine and clevidipine), are selective for vascular smooth muscle over the myocardium, with little if any activity in cardiac muscle or the sinoatrial node; thus, they have little effect on heart rate and no effect on myocardial contractility.¹⁶ The vascular smooth muscle relaxation without associated cardiac effects makes this class favorable for the treatment of hypertensive emergencies.

Nicardipine hydrochloride is a dihydropyridine CBB that acts primarily as a systemic, cerebral, and coronary artery vasodilator. The greater water solubility of this drug compared to other calcium channel blockers (e.g., nifedipine) allows intravenous administration with a short onset (5-15 min) and short duration of action; therefore, titration to a therapeutic effect is easy. Nicardipine readily crosses the blood-brain barrier and relaxes vascular smooth muscle, especially in regions of ischemic tissue. The medication acts as a vasodilator of small resistance cerebral arterioles but does not change intracranial volume or intracranial pressure with preservation of cerebral oxygenation.¹⁷ In comparison to SNP, nicardipine appears to offer equal efficacy with the advantage of avoiding the toxic metabolites of SNP, less frequent dose adjustments, and a decreased risk of increased intracranial pressure as

reported with SNP. Nicardipine has been shown to increase coronary blood flow with a favorable effect on myocardial oxygen demand.¹⁸ Nicardipine is metabolized by the liver, and excretion can be impaired in patients with liver disease.

Clevidipine is a third-generation dihydropyridine CCB available as a racemic mixture with poor water solubility, so the drug is administered by continuous IV infusion in a lipid emulsion. A new formulation of clevidipine has been available in the United States since 2011 and contains a retardant (0.005% disodium edetate) that inhibits microbial growth for up to 12 hours. Clevidipine reduces afterload without adversely affecting cardiac filling pressures or causing reflex tachycardia.¹⁹ Clevidipine has a rapid onset (~2-4 min) and offset of action (~5-15 min). It undergoes rapid ester hydrolysis by arterial blood esterases to form inactive metabolites, making medication clearance independent of renal or hepatic functional status.

Clevidipine is contraindicated in patients with allergies to soybeans, soy products, eggs, or egg products and in patients with defective lipid metabolism. Due to lipid-load restrictions, no more than 1000 mL or an average of 21 mg/h of clevidipine infusion is recommended per 24-hour period.

Clevidipine has shown favorable results in adult cardiac surgery patients with acute perioperative or postoperative hypertension, in acute hypertensive heart failure, and in patients with intracranial hemorrhage.^{20,21} Elevated triglyceride levels have been reported in patients who received clevidipine but these resolved with discontinuation of the medication.

Beta-Blockers

Esmolol is a short-acting, cardioselective beta-blocker with a rapid onset (<1 min) and short duration of action (10-20 min) that is only administered by continuous infusion. The short half-life requires bolus administration with each infusion titration. Esmolol reduces blood pressure, heart rate, and cardiac output and must be avoided in patients with bradycardia or impaired left ventricular function. Esmolol is optimally used in patients with tachycardia, hypertension, and normal to elevated cardiac output. Esmolol is rapidly cleared by red blood cell esterases and is independent of renal or hepatic function.

Labetalol is an oral and parenteral agent that acts as an alpha- and nonselective beta-adrenergic blocker with an alpha-to-beta blocking ratio of 1:7.²² The blood pressure-lowering effect is produced through a reduction in systemic vascular resistance without a compensatory increase in heart rate. In contrast to traditional beta-blockers, labetalol is associated with preservation of cardiac output. The hypotensive effect of labetalol has an onset of 2-5 min, peak effect at 5-15 min, and duration of ~2-6 hours. Labetalol has very little effect on cerebral circulation and is thus not associated with an increase in intracranial pressure in the normal brain. The drug has minimal placental transfer and has been used effectively in pregnancy-associated hypertension. The drug has been used effectively in patients with end-organ dysfunction in the setting of acute neurologic injury, pheochromocytoma, dissecting aneurysm, and eclampsia. The primary contraindication to the use of the medication relates to its nonselective beta-blocking

properties. The drug should be used cautiously in patients with reactive airway disease and heart block.

Miscellaneous Medications

Enalapril is an intravenously administered angiotensin converting enzyme (ACE) inhibitor. This medication reduces renin-dependent vasopressor activity, blocks the conversion of angiotensin I to angiotensin II, and blocks the degradation of bradykinin. ACE inhibitor administration is associated with a decrease in systemic vascular resistance, with minimal change in heart rate, cardiac output, or left ventricular filling pressure. Enalapril is effective in patients with low to normal renin levels and hypertension. The peak effect of enalapril may not be seen for up to 4 hours, with a duration of 12-24 hours. These pharmacokinetic parameters limit the drug titration in the acute setting of hypertensive emergency. ACE inhibitors are contraindicated in the setting of renal artery stenosis and pregnancy.

Phentolamine is a rapid-acting, alpha-adrenergic blocker. Phentolamine is often considered the drug of choice for hypertensive emergencies secondary to pheochromocytoma, MAO-tyramine interactions, and clonidine rebound hypertension.

Hydralazine is a direct-acting vasodilator with a latent onset (5-15 min) and a prolonged effect (~12-hour half-life) that can be highly variable. Because of hydralazine's prolonged and unpredictable antihypertensive effects, this medication is best avoided in the management of hypertensive emergency.

Diuretics should be avoided initially in the acute management of hypertensive emergency in the absence of pulmonary edema or renal parenchymal disease. Volume depletion is typical in HE patients and these patients are susceptible to hypotension and compromised perfusion if vasodilators and diuretics are initiated together.

KEY POINTS

1. Although hypertensive emergency (HE) is typically associated with a blood pressure elevation >180/110 mm Hg, the diagnosis of HE is based on the patient's clinical signs and symptoms rather than a specific blood pressure level.
2. Clinical conditions associated with HE include hypertensive encephalopathy, intracranial hemorrhage, acute coronary syndrome, acute pulmonary edema, aortic dissection, acute renal failure, and eclampsia.
3. Patients with hypertensive urgency (without end-organ dysfunction) are best treated with oral agents, allowing a gradual reduction in the blood pressure over 24-48 hours.
4. Patients with hypertensive emergency (HE), should be treated with short-acting titratable medications that are administered in a monitored environment, as hypotension and compromised organ perfusion must be avoided.

Assessment of hemodynamics is an important skill in the critical care setting. The goal of hemodynamic monitoring in a critically ill patient is to ensure adequate tissue oxygen delivery and end organ perfusion. Low systemic arterial blood pressures are commonly encountered in the clinical setting, and a thoughtful, systematic approach should be utilized.

INITIAL EVALUATION

Initial evaluation usually begins with assessment of blood pressure (BP) readings. However, one should not rely solely on these readings, as there is no “normal” BP for all patients, and a BP value in the “normal” range does not always equate with adequate tissue perfusion. For example, a patient with a history of poorly controlled chronic hypertension may be normotensive, not yet in critical condition, but cannot meet his or her body’s oxygen demand, resulting in evidence of significant anaerobic metabolism referred to as *cryptic shock*.¹ Conversely, a patient with cirrhosis or a pregnant patient may have adequate perfusion despite having a lower than normal BP.

Additionally, attention should also be given to the mean arterial pressure (MAP). It is important to keep in mind that the MAP is the sum of 2/3 diastolic and 1/3 systolic pressure. The MAP is the main determinant of the perfusion pressure or what pressure the organ sees. Safe levels of hypotension have historically been estimated to be anything greater than 2/3 MAP.^{2,3} Even more recently, it was found that an MAP less than 55 mm Hg during noncardiac surgery is independently associated with an increased risk of kidney and myocardial injury and has a moderate association with duration of surgery.⁴ A good initial goal should be to restore the patient to an MAP of 65 to 70 mm Hg, but the level should be adjusted to restore tissue perfusion as assessed on the basis of mental status, appearance, urine output, etc.⁵ Therefore, hypotension triage needs to be quick and purposeful in order to prevent potentially damaging long-term sequelae.

An initial bedside assessment of tissue perfusion should include evaluation of mental status, urine output, and skin findings (e.g., temperature, diaphoresis, mottling, and capillary refill). If any of these parameters is abnormal, a more urgent approach to treatment must be taken. A focused cardiac and pulmonary examination is essential: presence of jugular venous distention, an S₃ or S₄ heart sound, new or worsening murmurs, or muffled heart sounds, crackles or rales. Furthermore, a finding of absent breath sounds could be equally important, suggesting a pneumothorax.

All patients should have adequate IV access, preferably two patent 18-gauge or larger catheters. The patient should be monitored using a standard ECG monitor and pulse oximetry. A 12-lead ECG should be performed looking for evidence of myocardial ischemia. Chest radiography should be done and supplemental oxygen should be given. Complete blood counts, serum chemistry, lactate, arterial blood gas, random cortisol, coagulation panels, and cardiac enzymes should be drawn as part of the initial workup.

WHAT IS THE CAUSE?

A review of cardiovascular physiology is essential in order to help focus the differential diagnosis of a hypotensive patient. A clinician’s initial evaluation should be a global assessment (Fig. 6-1) of systemic vascular resistance (SVR) and cardiac output (CO). It is important to recall that $\text{pressure} = \text{flow} \times \text{resistance}$, where flow is CO and resistance is SVR.

Because CO is determined by stroke volume (SV) \times heart rate (HR), the presence of hypotension means that at least one of these parameters (e.g., SV, SVR, or HR) is abnormal.⁶ Assessment of HR is obvious by palpation of pulses or cardiac monitoring; however, assessing SV and SVR can be more challenging. Attention should be paid to systolic (SBP) and diastolic (DBP) blood pressures in the context of pulse pressure (PP = SBP – DBP). Diastolic pressure is a reasonable surrogate for systemic vascular resistance (SVR).

During systole, the SV is ejected into the proximal arterial conduits. Because more blood is being ejected than the peripheral circulation can accommodate in the arterioles, the arterial walls distend, increasing SBP in a way that is directly proportional to the SV and indirectly proportional to the capacitance (C) of the arterial wall. This relationship is represented by the following formula⁶:

$$\text{SBP} = \text{SV} \div C$$

That is, for a fixed SV, if capacitance is higher, the SBP is lower.

During diastole, the portion of the SV that was “stored” by the distention of the arterial walls during systole fills the peripheral arterioles, leading to a progressive decrease in BP until the next systolic phase. This is the diastolic pressure, a parameter that is directly related to the SVR and capacitance (i.e., low diastolic pressure = low SVR and/or capacitance).⁶ When using these basic cardiovascular principles to understand the cause of hypotension, it is important to remember the following: (1) capacitance does not change from heartbeat to heartbeat and (2) SV depends on preload, afterload, and contractility.

Low SVR is characteristic of a number of pathologic conditions, including sepsis, adrenal insufficiency, vasodilating medications, neurogenic shock, post-cardiopulmonary bypass (CPB) vasoplegia, and severe liver dysfunction. Decreased SVR should be suspected in the presence of a widened pulse pressure and low diastolic pressure.^{7,8}

Reduced SV can be due to decreased preload, decreased contractility, or increased afterload. The most common cause of inadequate preload is hypovolemia. Other causes of inadequate preload include increased intrathoracic pressure due to dynamic hyperinflation in mechanically ventilated patients^{9,10} or tension pneumothorax, pulmonary embolism,¹¹ mitral valve stenosis,¹² cardiac tamponade,¹³ and right ventricular failure.¹⁴ Decreased contractility can be caused by myocardial ischemia or infarction, cardiomyopathy, myocarditis, negative inotropic drugs, myocardial stunning after CPB, and direct myocyte toxins such as chemotherapeutic agents and inflammatory mediators (e.g., tumor necrosis factor [TNF] and interleukin 1-beta [IL-1 β]).¹⁵ A reduction in SV can be identified by decreased systolic BP and normal or narrow pulse pressure.

TREATMENT

Hypotension has been associated with higher morbidity and mortality in a variety of disease states, so until proven otherwise, hypotension should be considered synonymous with hypoperfusion and thus treated aggressively. A trial of at least 1.0 L of crystalloid should be infused to treat hypotension; the fear of pulmonary edema should not preclude the use of volume expanders in a patient who is not perfusing adequately.¹

There are several tools that aid in the workup of the hypotensive patient. The use of ultrasound at the bedside to evaluate inferior vena cava diameter (IVCd) has proven to be an accurate metric of volume responsiveness in mechanically ventilated and spontaneously

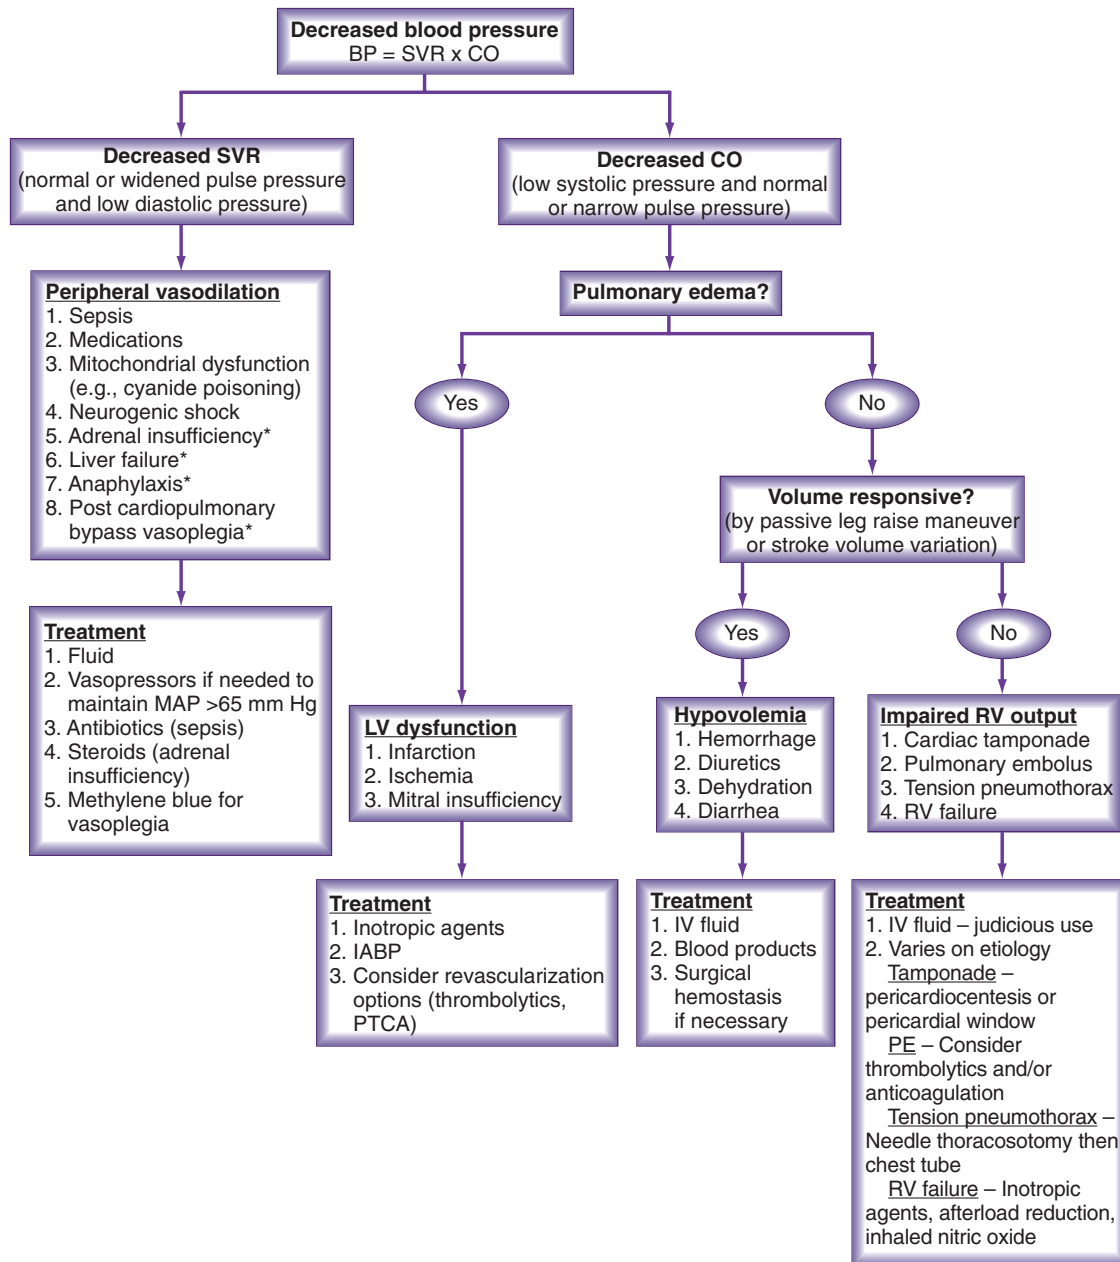

FIGURE 6-1 ■ Initial approach to a patient with low systemic arterial blood pressure. *Adrenal insufficiency, liver failure, post-cardiopulmonary bypass vasoplegia, and anaphylaxis are commonly listed as vasodilatory shock; however, data are inconclusive, and components of other types of shock (hypovolemic, cardiogenic) may also be present. BP, blood pressure; CO, cardiac output; IABP, intraaortic balloon pump; IV, intravenous; LV, left ventricle; MAP, mean arterial pressure; PE, pulmonary embolism; PTCA, percutaneous transluminal coronary angioplasty; RV, right ventricle; SVR, systemic vascular resistance.

breathing patients.¹⁶ IVCd is measured subcostally, approximately 0.5–4.0 cm below the junction of the IVC and right atrium, in the longitudinal direction at a perpendicular angle to the IVC, and is calculated as “the change” in IVCd during inspiration as compared with baseline (expiration).¹⁶ Patients with a large variation (>50%) will most likely respond to additional volume.¹⁷ Also, using ultrasound to perform a focused cardiac examination can identify the global quality of contractility, ventricular size and volume, obvious wall motion abnormalities, significant valvular abnormalities, and the presence of a pericardial effusion.¹⁸

Another method by which the clinician can evaluate “volume responsiveness” is the passive leg raise (PLR) test. In the nonintubated, supine patient, elevating the patient’s legs at a 45-degree angle above the plane of the bed will cause a rapid temporary increase in venous return to the heart and an increase in CO, which has been shown to correlate with a 500-cc bolus of normal saline.¹⁶ This maneuver increases pulse pressure in “responders.” An increase in pulse pressure of more than 9% noted before and after the passive leg lifts will identify patients who are likely to respond to additional IV fluid administration.^{19,20}

While more invasive than the above, pulse contour analysis (PCA) has emerged as an accurate method for measuring cardiac performance (SV, CO, CI) and also measures pulse pressure or stroke volume variation in the intubated and mechanically ventilated patient. By observing the undulation of the arterial line monitor for 30 seconds and observing the variability throughout the respiratory cycles, a decrease of 13% or more in stroke volume during the inspiratory cycle correlates with preload responsiveness of stroke volume. This variation represents a decrease in venous return in conjunction with the increased intrathoracic pressure during the inspiratory phase of ventilation. This measurement is only accurate when the heart rhythm is regular, so it is an unreliable index of preload responsiveness in patients with many kinds of arrhythmias, in the presence of an intraaortic balloon pump, or when there is loss of integrity in the arterial wave-

form. It is also only accurate in mechanically ventilated patients who are not experiencing large variations in intrathoracic pressures.^{21,22}

In those patients where a low SVR is suspected as the primary cause of hypotension, the treatment is different. Large amounts of additional IV fluid alone will not adequately increase the BP to maintain tissue perfusion. Vasoconstrictor agents (e.g., norepinephrine, dopamine, phenylephrine, and vasopressin) will be required in these patients. In certain specific cases, other pharmacologic adjuncts may be helpful. Low-dose hydrocortisone in vasoconstrictor-resistant septic shock²³ and methylene blue in post-CPB vasoplegia are two examples.²⁴

Many occurrences of hypotension may have some qualities of both decreased SV and decreased SVR. However, by using a systematic approach, the clinician can rapidly start diagnostic and therapeutic measures needed to treat tissue hypoperfusion.

Cardiac arrhythmias are common in the intensive care unit (ICU), and the incidence can approach 40%. Critically ill patients are at a greater risk for developing arrhythmias because of elevated catecholamine levels, electrolyte imbalances, metabolic disturbances, the presence of invasive lines, polydrug therapy, and rapidly changing intravascular volume status.¹ Depending on the type of arrhythmia and the degree of physiologic reserve, patients can be asymptomatic or present with profound hemodynamic instability, including cardiopulmonary arrest. The presence of arrhythmias has been associated with prolonged hospital stays, increased risk of neurologic deficits, and greater in-hospital mortality rates.^{1,2} While definitive diagnosis requires an electrocardiogram (ECG), arrhythmias are generally classified according to their heart rate into one of two categories: tachycardias (heart rate > 100 beats per minute [bpm]) and bradycardias (heart rate < 60 bpm).

TACHYCARDIA

A key principle in managing the patient with tachycardia is to determine whether end-organ perfusion is being compromised as a result of the tachycardia or if the increase in heart rate represents a normal physiologic response to hemodynamic instability. Further evaluation includes identification of the type of tachycardia based on morphologic features. Specifically, tachycardias can be classified as supraventricular or ventricular in origin on the basis of the QRS complex. Tachycardia with a narrow QRS complex (<120 milliseconds [ms]) denotes a supraventricular tachycardia (SVT), while wide complex tachycardias (>120 ms) indicate either ventricular tachyarrhythmias or SVTs with associated conduction abnormalities.³

Sinus Tachycardia

Sinus tachycardia represents a form of SVT that occurs as a result of the impact of various stimuli on sinus node pacemaker cells.⁴ In critically ill patients, common causes of sinus tachycardia include hypoxia, acidosis, hyperthermia, pain, hypovolemia, and hyperthyroidism.³ Furthermore, a number of medications including inotropes, vasopressors, and anticholinergics can produce sinus tachycardia. Often sinus tachycardia is the appropriate physiologic response to an ongoing disease process, and treatment should be directed toward the underlying cause. Inappropriate treatment of sinus tachycardia may lead to hemodynamic collapse in situations where the tachycardic response was appropriate in order to compensate for hypovolemia or low cardiac output states. Conversely, sinus tachycardia can produce myocardial ischemia and decrease diastolic filling in patients with coronary artery disease. In these situations, β -blocker administration may decrease myocardial oxygen demand and mitigate the development of ischemia.³ The development of sinus tachycardia in a critically ill patient should prompt both a thorough review of medications and evaluation for evolving disease processes.

Supraventricular Tachycardia

Aside from sinus tachycardia, regular narrow complex SVT is typically associated with a reentry pathway. In hemodynamically stable patients, exercises that increase vagal tone will slow conduction through the

atrioventricular (AV) node and can effectively terminate many SVTs.⁴ Sequential carotid sinus massage (e.g., application of unilateral pressure on the carotid artery) and Valsalva techniques (e.g., expiration against a closed glottis) are examples of vagal maneuvers that can produce rapid arrhythmia resolution in the absence of pharmacologic therapy.⁵ If the arrhythmia is refractory to these interventions, the administration of an AV nodal blocking agent (e.g., adenosine, calcium channel blockers, and β -blockers) can be both diagnostic and therapeutic. Non-AV nodal dependent SVTs can be identified as conduction through the AV node is blocked, allowing visualization of the underlying atrial rhythm. Adenosine has the advantage over other AV nodal blockers as having the shortest onset and half-life times, although episodes of severe bronchospasm and degeneration into ventricular arrhythmias have been reported.^{3,5} For recurrent episodes of SVT following the use of adenosine, non-dihydropyridine calcium channel blockers or β -blockers can be used for both termination and suppression therapy. If the SVT remains refractory to AV nodal blockade, antiarrhythmic therapy with amiodarone or procainamide or catheter ablation may be required for definitive management.^{1,3}

Atrial Fibrillation

Atrial fibrillation (AF) is the most common sustained arrhythmia both in the general population and among adult ICU patients.^{1,6} AF occurs in up to 31% of critically ill patients, and ICU-specific risk factors include hypotension, the use of vasopressors or inotropes, septic shock, hypervolemia, heart failure, electrolyte derangements, and postoperative status.¹ Electrocardiographic features of AF include the lack of organized P waves, high-frequency fibrillation waves, and an irregular ventricular response.⁷ Physiologically, AF is characterized by the loss of the atrial contribution to ventricular filling, which normally accounts for approximately 25% of left ventricular end-diastolic volume.¹ This loss can be especially significant in patients with diastolic dysfunction, and pulmonary edema can develop as a result of the acute rise in left atrial pressure. Additionally AF is associated with increased risks of non-ST elevation myocardial infarction (NSTEMI), stroke, heart failure, longer hospital stays, reduced quality of life, and increased mortality.^{6,7,8}

In unstable patients with hemodynamic instability, AF should be treated with immediate synchronized cardioversion. Management of the hemodynamically stable patient with AF involves three treatment principles: rate control, rhythm control (cardioversion), and systemic anticoagulation. When comparing these strategies, rate control is not inferior to rhythm control for the management of AF.⁹ Rate control can be accomplished with the use of a number of medications, and β -blockers should be considered first-line agents. They provide more successful rate control than calcium channel blockers, and they may be especially effective in the postoperative period when sympathetic tone is high.^{1,3} If β -blockers are contraindicated or ineffective, non-dihydropyridine calcium channel blockers can be used as alternatives. Given their negative inotropic effects, calcium channel blockers should be avoided in patients with reduced ejection fraction. Amiodarone is an effective option for cardioversion in patients with depressed ejection fraction or those who are receiving inotropic support; however, pulmonary and thyroid toxicity can develop following its administration. Cardioversion rates with the use of amiodarone can approach 80%. The

time period between amiodarone administration and cardioversion can be prolonged, making amiodarone a poor choice if rapid conversion is needed.³ Digoxin has been traditionally recommended as an option for rate control; however, it is less efficacious in patients with high sympathetic tone, making its effectiveness in the ICU setting often marginal.³ Furthermore, the use of digoxin in patients with AF is associated with an increased risk for mortality.¹⁰ If AF persists for greater than 48 hours, systemic anticoagulation should be considered. The risk of stroke in nonanticoagulated patients with AF is 0.05% per day, but the risk of bleeding should be weighed against the risk of stroke for each patient before anticoagulation is initiated.³

Atrial Flutter

Atrial flutter is a reentry-mediated, narrow complex tachycardia that is characterized by a sawtooth pattern on the ECG. Atrial rates typically range from 250 to 350 bpm, and patients often present with 2:1 AV conduction with a corresponding ventricular rate of approximately 150 bpm.³ In critically ill patients with high levels of sympathetic tone, ventricular rates may be more rapid. Pharmacologic and anticoagulation management principles for atrial flutter are similar to those for AF, although it may be more difficult to achieve rate control in atrial flutter.¹ Furthermore, electrical cardioversion of atrial flutter can often be accomplished with lower energies than those required for AF. Success rates of electrical cardioversion in atrial flutter can range from 95% to 100%.³

Ventricular Tachycardia

Ventricular tachycardia (VT) accounts for 80% of all wide complex tachycardias.¹ VT can be classified as either monomorphic or polymorphic on the basis of the QRS morphology. Monomorphic VT is characterized by a uniform QRS morphology, and the approach to treatment is based on the presence or absence of hemodynamic instability.³ If the patient is unstable or manifesting with evidence of hypoperfusion, then synchronized cardioversion is indicated. If the patient presents with pulseless VT, then unsynchronized cardioversion should be performed. Stable monomorphic VT can be managed with antiarrhythmics, and the choice of agent depends on the degree of left ventricular dysfunction. Procainamide, amiodarone, sotalol, and lidocaine are treatment options for patients with preserved function. Sotalol and procainamide should be avoided in patients with impaired left ventricular function.^{3,5} Because of its superior efficacy, amiodarone is typically the drug of choice for stable monomorphic VT.¹ In addition to pharmacologic therapy, correction of electrolyte abnormalities and discontinuation of proarrhythmic agents are important management principles and should be performed concurrently.

Polymorphic ventricular tachycardia (PVT) is characterized by beat-to-beat variations in QRS morphology.¹ Unlike its monomorphic counterpart, PVT is almost never asymptomatic, and synchronized cardioversion should be performed immediately.³ PVT can occur in the setting of either a normal (<460 ms) or prolonged QT interval (>460 ms). When associated with QT prolongation, the syndrome is termed *torsades de pointes*, and management should be directed toward correcting the QT interval. Discontinuation of QT-prolonging medications, correction of electrolyte abnormalities, and magnesium administration should be performed in patients with PVT.^{1,5} If the arrhythmia persists, isoproterenol administration or overdrive pacing can be performed to increase the heart rate and shorten the QT interval.³

BOX 7-1

Common Causes of Bradycardia in the ICU

Medications: antiarrhythmics, β -blockers, calcium channel blockers, clonidine, dexmedetomidine, digoxin, lithium, opioids, phenytoin, and propofol
 Age-related degeneration
 Cardiac ischemia
 Electrolyte abnormalities
 Elevated intracranial pressure
 Elevated vagal tone
 Endotracheal intubation
 Hypertension
 Hypothermia
 Hypothyroidism
 Hypoxia
 Inflammatory disease
 Obstructive sleep apnea
 Post cardiac surgery

BRADYCARDIA

In general, bradyarrhythmias arise from abnormalities in impulse generation or impulse conduction. Diminished sinus node function manifests with sinus bradycardia, while heart block occurs as a result of disease in the AV node or His-Purkinje system.¹¹ The degree of heart block is determined by the extent of AV impulse conduction. In first-degree heart block, all impulses are conducted, but the rate of conduction is slowed. This condition is reflected by a prolonged PR interval (>200 ms) on the ECG. Second-degree heart block is characterized by intermittent AV conduction and can be divided into two types. Type I second-degree block presents with progressive PR interval prolongation prior to a nonconducted P wave. Type II second-degree block presents with constant PR intervals before and after a nonconducted P wave. Third-degree heart block presents with absent AV conduction.¹¹ In critically ill patients, bradycardia is often a consequence of pharmacologic therapy, underlying comorbid disease, or progressive respiratory failure. Scenarios associated with the development of bradyarrhythmias include elevated intracranial pressure, high vagal tone, hypothyroidism, hypothermia, and cardiac ischemia (Box 7-1). As with tachycardia, the most important principle in evaluating the patient with bradycardia is to determine if perfusion is being compromised as a result of the arrhythmia. Ultimately, appropriate treatment is dependent both on the type of bradycardia and the context in which it arises.

No treatment is indicated for asymptomatic bradycardia. Bradycardia may decrease cardiac output in patients with fixed stroke volumes, and the initial treatment for bradycardia-induced hypoperfusion is intravenous atropine.³ Medications with β -agonist activity (e.g., dopamine, dobutamine, isoproterenol, and epinephrine) can provide temporary support if the bradyarrhythmia is refractory to atropine administration. Concurrent investigation into the underlying cause of the bradycardia should be performed, especially focusing on medication side effects and declining respiratory status. The ECG should then be evaluated for the presence of myocardial ischemia and heart block. Patients with first-degree and type I second-degree blocks can often be managed conservatively. Type II second-degree and third-degree blocks require pacemaker placement.¹¹ In the acute setting, temporary pacing may be required to restore end-organ perfusion.¹ Depending on the clinical scenario, temporary pacing in the ICU can be accomplished using transcutaneous, transvenous, and epicardial modalities.

KEY POINTS

1. Determination of whether tachycardia is the cause of hemodynamic instability or the physiologic response to instability is important.
2. Sinus tachycardia is often a manifestation of an ongoing disease process and is best managed by treating the underlying cause.
3. Management of the hemodynamically stable patient with atrial fibrillation involves three treatment principles: rate control, rhythm control, and systemic anticoagulation.
4. Discontinuation of QT-prolonging medications, correction of electrolyte abnormalities, and magnesium administration should be performed in patients with polymorphic ventricular tachycardia.
5. No treatment is indicated for asymptomatic bradycardia. The initial treatment for symptomatic bradycardia is intravenous atropine.
6. Bradycardia that is refractory to atropine administration can be treated with inotropes and temporary pacing.

To allow for normal aerobic cellular metabolism, oxygen needs to be transported from ambient air into the circulatory system before it is delivered to the end organs. Reduced arterial oxygen levels either in dissolved form (partial pressure of oxygen [PaO_2] less than 80 mm Hg) or percent bound to hemoglobin (SaO_2 less than 95%) define *hypoxemia*. In contrast, inadequate oxygen content of the tissue beds of organs defines *hypoxia*. Since the lungs facilitate the transport of oxygen from ambient air to the circulatory system, respiratory failure commonly results in hypoxemia and often requires intensive care management. Left unchecked, arterial hypoxemia can lead to end-organ hypoxia and dysfunction, most devastatingly anoxic brain injury and cardiac arrest.

SaO_2 varies with PaO_2 in a nonlinear relationship, affected by temperature, partial pressure of carbon dioxide in arterial blood (PaCO_2), pH, and 2,3-diphosphoglycerate concentration (Fig. 8-1). As a result, patients can have a higher or lower SaO_2 for a given PaO_2 , depending on the existing metabolic conditions. The critical threshold of PaO_2 is 60 mm Hg, below which further decrements in PaO_2 result in more significant reductions in SaO_2 compared to when PaO_2 is >60 mm Hg.

Because arterial oxygen is overwhelmingly bound to hemoglobin (Hb) instead of being dissolved in plasma, SaO_2 is considered a better reflection of arterial oxygen content (CaO_2) compared to PaO_2 :

$$\text{CaO}_2 = (\text{SaO}_2 \times \text{Hb} \times 1.34) + (0.003 \times \text{PaO}_2),$$

where 1.34 is the amount of oxygen (mL) per gram of hemoglobin. While PaO_2 is less of a factor for CaO_2 compared to SaO_2 , increasing supplemental oxygen to increase PaO_2 to supranormal levels can improve the time window for medical interventions that may result in hypoxemia, such as endotracheal intubation or bronchoscopy.

PaO_2 and SaO_2 are measured by arterial blood gas analysis, which is invasive and not measured continuously. Peripheral oxygen saturation (SpO_2) serves as a surrogate measure of SaO_2 and can be measured noninvasively and continuously with a pulse oximeter. Pulse oximetry determines SpO_2 using spectrophotometry to detect oxyhemoglobin (peak absorption at 940 nm) and deoxyhemoglobin (peak absorption at 660 nm) isolated to the pulsatile signal through tissue (e.g., fingertip or earlobe). As a result, its accuracy may be affected by various factors. The SpO_2 can present a falsely low reading if there is a poor pulsatile waveform, which can occur when there is poor cutaneous perfusion. Light transmission through the tissues of the fingertip can be decreased by dark blue or black nail polish. Methemoglobinemia can result in a falsely low SpO_2 reading, whereas carboxyhemoglobinemia can result in a falsely elevated SpO_2 reading.¹

It takes seconds to minutes for the SpO_2 to reflect treatment changes for arterial hypoxemia (e.g., increase or decrease of supplemental oxygen). Longer response times are expected if the probe is placed farther away from the heart, when the blood flow to the area of the probe is reduced, and when there is reduced cardiac output.^{2,3} The delay between a treatment intervention and the SpO_2 response needs to be considered when making decisions regarding the escalation and de-escalation of oxygen therapy.

CAUSES OF ARTERIAL HYPOXEMIA

Once hypoxemia is detected, in addition to initiating oxygen therapy, the cause for hypoxemia must be determined. Etiologies for hypoxemia can be categorized as follows:

1. Reduced fraction of inspired oxygen (FiO_2) or partial pressure of oxygen (e.g., breathing at elevation)
2. Hypoventilation (e.g., central respiratory depression, neuromuscular weakness, and chest wall deformity)
3. Diffusion impairment
4. Ventilation/perfusion mismatch
5. Presence of a pulmonary shunt

Reduced Alveolar Oxygenation and Hypoventilation

Alveolar oxygenation (PAO_2) is defined by the equation:

$$\text{PAO}_2 = \text{FiO}_2 (\text{Patm} - \text{PH}_2\text{O}) - \text{PaCO}_2 / \text{RQ},$$

where FiO_2 is the concentration of inspired oxygen, P_{atm} is the atmospheric pressure, PH_2O is the partial pressure of water, and RQ is the respiratory quotient.^{4,5} RQ represents the amount of oxygen consumed relative to the amount of carbon dioxide produced when nutrients are metabolized. RQ is generally assumed to be 0.8, under the assumption that glucose is the predominant metabolic fuel. Under normal conditions at sea level,

$$\text{PAO}_2 =$$

$$0.21 (760 \text{ mm Hg} - 47 \text{ mm Hg}) - (40 \text{ mm Hg} / 0.8) \approx 100 \text{ mm Hg}.$$

According to the equation, PAO_2 decreases with decreased FiO_2 and/or decreased Patm , which can occur when climbing at high altitudes.⁶ PAO_2 can also be reduced with increased PaCO_2 , which in turn is determined by the following equation:

$$\text{PaCO}_2 =$$

$$\text{CO}_2 \text{ production} \div (\text{respiratory rate} \times [\text{tidal volume} - \text{dead space}]).$$

Thus, PaCO_2 increases with an increase in production, a decrease in the minute ventilation, and/or an increase in dead space ventilation. Hypoventilation from central respiratory depression, neuromuscular weakness, or other conditions that decrease minute ventilation or increase dead space ventilation can therefore lead to hypoxemia from reduced PAO_2 .

To summarize, reduced inspired oxygen content and reduced ventilation can both contribute to arterial hypoxemia. However, in the case where neither of these is a contributing factor, hypoxemia must be the result of either diffusion impairment or more commonly a ventilation/perfusion mismatch.

Diffusion Impairment

Diffusion impairment is the least likely cause of hypoxemia in the intensive care unit and can result from an increase in the diffusion distance between the alveolar space and the capillary lumen, a reduction in the total alveolar surface area, or a reduction in the capillary transit time. Increases in sympathetic tone due to fever, anemia, work of breathing, or sepsis can each increase the cardiac output and heart rate, resulting in faster transpulmonary transit times. With less opportunity for alveolar oxygen to diffuse into the red blood cells, diffusion capacity is reduced and hypoxemia ensues.

FIGURE 8-1 ■ Oxygen saturation varies with the PaO_2 in a nonlinear relationship and is affected by temperature, PaCO_2 , pH, and 2,3-diphosphoglycerate (2,3-DPG) concentration.

FIGURE 8-3 ■ Blunted response to increasing inspired oxygen concentration. A patient with a shunt greater than 50% has little response to increasing FiO_2 .

FIGURE 8-2 ■ Decrease in PaO_2 with increasing shunt fraction.

Ventilation/Perfusion Mismatch and Shunting

The most common cause of hypoxemia is ventilation/perfusion mismatch, specifically when areas of reduced alveolar ventilation have relatively preserved or even supranormal levels of blood perfusion. Typically, alveolar filling or collapse (due to edema, pneumonia, hemorrhage, tumor, or atelectasis) results in unventilated or poorly ventilated areas of lung. Under normal conditions, the hypoxic pulmonary vasoconstriction reflex reduces perfusion to under-ventilated areas of lung to minimize hypoxemia, but if the adaptive mechanisms that are responsible for hypoxic vasoconstriction are dysfunctional, then perfusion of under-ventilated areas can continue. As a consequence, an increased fraction of the cardiac output will not participate in gas exchange. The portion of cardiac output that does not participate in gas exchange is called the shunt fraction. The normal shunt fraction is approximately 3%, and this small amount of shunt is due to the bronchial arterial circulation. Reduced ventilation of perfused alveoli increases the shunt fraction. As the shunt fraction increases, PaO_2 decreases (Fig. 8-2), and there is a blunted response to increases of FiO_2 . When the shunt fraction is $>50\%$, there is little response to increases of FiO_2 (Fig. 8-3). As such, severe ventilation/perfusion mis-

matching can result in a shunt where hypoxemia is refractory to treatment with supplemental oxygen.

Anatomic right-to-left shunts, such as intracardiac shunts and intrapulmonary shunts resulting from either arterial-venous malformations or end-stage liver disease, can also result in hypoxemia refractory to supplemental oxygen.

Pulmonary perfusion is normally distributed in a dependent manner, with dependent areas preferentially perfused compared to nondependent areas. As a result, changes in the patient's physical position can lead to changes in arterial oxygenation, depending on the location and distribution of the under-ventilated lung areas or the regions of intrapulmonary shunt. If the patient is positioned such that the under-ventilated areas of the lung or the regions with the intrapulmonary shunt are located in a more dependent way, then preferential perfusion of these areas will result in an increased shunt fraction and worse hypoxemia. For example, an intrapulmonary shunt in the bases of the lungs can lead to platypnea-orthodeoxia, i.e., dyspnea and hypoxemia that are worse in the upright position compared to the supine position.

While reduced ventilation with preserved perfusion typically causes hypoxemia, preserved alveolar ventilation with reduced perfusion typically results in increased functional dead space, and thus hypercarbia, which is usually overcome by increased minute ventilation. Areas of reduced perfusion can result from pulmonary vascular disease such as pulmonary emboli, pulmonary arterial hypertension, or reduced cardiac output. Pulmonary vascular disease per se does not result in hypoxemia unless there is also reduced alveolar ventilation or diffusion impairment. Another way pulmonary vascular disease can lead to hypoxemia is if high pulmonary vascular resistance results in elevated right heart pressures and an intracardiac right-to-left shunt via, for example, a patent foramen ovale.

MEASURES OF ARTERIAL HYPOXEMIA

Aside from PaO_2 , SaO_2 , and SpO_2 , hypoxemia can be assessed by other measures. The difference between the PAO_2 and the PaO_2 , termed the *A-a gradient*, is used to estimate the extent of pulmonary pathophysiology and to exclude the effects of hypercarbia on PaO_2 .^{4,5} However, the A-a gradient increases with age or increasing FiO_2 , limiting its reliability.^{7,8} Nevertheless, the upper limit of the normal A-a gradient can be estimated using the following equation:

$$\text{A-a gradient} < (\text{age} \div 4) + 4.$$

The $\text{PaO}_2/\text{FiO}_2$ ratio and $\text{PaO}_2/\text{PAO}_2$ ratio are also used to describe the severity of hypoxemia. They both are influenced by increasing FiO_2 .^{7,9}

MANAGEMENT OF ARTERIAL HYPOXEMIA

If a patient has low SpO_2 , the initial treatment is supplemental oxygen with observation of the response, pending evaluation of the hypoxemia. If the response to the initial increase in FiO_2 is poor, a better response may be achieved by increasing the flow rate of supplemental oxygen (e.g., using a high-flow nasal cannula or Venturi mask) or using

a reservoir of 100% oxygen (i.e., using a “nonrebreather mask”). If the response to the escalation of FiO_2 is poor, then the patient likely has severe ventilation/perfusion mismatching or a true right-to-left shunt. Satisfactory improvement in arterial oxygenation under these conditions usually requires positive pressure ventilation and the application of positive end-expiratory pressure (PEEP) using noninvasive ventilation or endotracheal intubation. If the patient has severe hypoxemia and is unstable, immediate bag-and-mask ventilation and early endotracheal intubation should take precedence over establishing a diagnosis.

Acute respiratory failure (ARF) is defined by the sudden onset of severe impairment of pulmonary gas exchange and is characterized by the inability of the lungs to meet the body's metabolic needs for the transport of oxygen (O_2) into the blood and/or removal of carbon dioxide (CO_2) from the blood. The diagnosis of ARF is based on the measurements of arterial blood gas (ABG) parameters (i.e., PaO_2 , $PaCO_2$, and pH). These values must be interpreted in relation to the patient's baseline status. As a final common pathway for a variety of illnesses, ARF is one of the most frequently encountered diagnoses in the intensive care unit (ICU), and its management represents one of the key aspects of critical care medicine. This chapter aims to tie together the physiology of breathing to the pathological processes that lead to ARF and to discuss the clinical approach to the patient with ARF.

ARF is one of the most common reasons for admission to the ICU, and almost 330,000 patients in the United States are annually diagnosed with this disorder.¹ More than half of the patients admitted to the ICU with stays >48 hours have ARF at some point during their hospitalization,² with overall mortality rates quoted as being $\geq 34\%$.²⁻⁵ Mortality significantly increases with age, preexisting comorbidities, and the presence of shock or multisystem organ failure.⁶ With the aging population in the United States, the incidence of patients with ARF is expected to increase by 80% over the next two decades.

COMPONENTS OF THE RESPIRATORY SYSTEM

Understanding the process of respiration is a key step in understanding and managing ARF. Respiratory control is established by the tight coordination of three groups of neurons in the medulla oblongata: a dorsal respiratory center that controls inspiration, a ventral respiratory group that controls expiration, and a pneumotaxic center that controls the rate and depth of breathing. In addition to neurons in the brainstem, a peripheral chemoreceptor system is located outside the brain in the form of carotid bodies and aortic bodies and detects subtle changes in PaO_2 . The neural impulses from the central nervous system (CNS) traverse the spinal cord and motor neurons, reaching and activating the diaphragm and other respiratory muscles. Contraction of the respiratory muscles creates negative pleural pressure by expanding the chest cavity and pushing the abdominal contents down. The negative pressure created in the thorax during inspiration leads to subatmospheric pressure in the alveoli, creating a gradient for the flow of inspired air toward the alveoli. Oxygen-rich inspired air allows the diffusion of O_2 from the alveoli to the blood through the alveolar-capillary membrane, where deoxygenated hemoglobin becomes saturated with O_2 and forms oxyhemoglobin.

O_2 is consumed by all human tissues, and oxygen consumption (QO_2) is dependent on gas exchange in the lungs. The average O_2 uptake of an adult is approximately 250 mL/min, although this depends upon numerous factors.⁷ Most (~98.5%) O_2 is carried to peripheral tissues via oxyhemoglobin, whereas the remainder is transported as O_2 dissolved in the fluid phase of blood. The total transport of O_2 by the arterial system is termed *oxygen delivery* (DO_2) and is normally several-fold higher than the O_2 demand of the peripheral tissues. However, O_2 utilization (VO_2) can become dependent on DO_2 in pathological conditions such as ARF.⁷⁻⁹ In these states, the relationship between oxygen delivery and oxygen demand can be disrupted due to decreased delivery or increased demand (Fig. 9-1).

DO_2 is dependent on cardiac output and arterial oxygen content (CaO_2), a value determined by the concentration of hemoglobin (Hgb) and oxygen saturation (SaO_2) (Fig. 9-2). The adequate perfusion of capillaries in the peripheral tissues allows for the liberation of O_2 from oxyhemoglobin.

PATHOPHYSIOLOGICAL PROCESSES LEADING TO ARF

It is important to understand the various etiologies and mechanisms leading to hypoxemia (Table 9-1), since interventions may vary and oxygen support may have different effects in different situations.

CLASSIFICATION OF ARF

Respiratory failure can be classified as acute or chronic. The clinical presentation of ARF is typically dramatic and obvious, often with profound derangements in ABG values. "Acute on chronic" respiratory failure represents an acute deterioration in the presence of preexisting chronic pulmonary disease and chronic respiratory dysfunction. Chronic respiratory dysfunction may present with markers of chronic hypoxemia (e.g., polycythemia or *cor pulmonale*) and may or may not require ICU care. Regardless of acuity, respiratory failure represents a life-threatening group of disorders for which inadequate management may lead to rapid clinical deterioration.

ARF has been classically described as one of two types: hypoxemic or hypercapnic failure. More recent classifications categorize ARF into four different types, based on the mechanism of hypoxemia.¹⁰ Table 9-2 describes differences among the four types of ARF with regard to the mechanism of hypoxemia, location of the abnormality, and most commonly seen clinical syndromes. Despite these categories, there exists considerable overlap in the different types of ARF. Furthermore, a given patient can have multiple types of ARF contributing to his or her clinical representation.

Type I or Classic "Hypoxemic" Respiratory Failure

Type I ARF is the most common form of respiratory failure and is defined by $PaO_2 < 60$ mm Hg, with normal or decreased $PaCO_2$. The primary abnormality is located in one of three sites: 1) inadequately oxygenated alveoli (due to low FiO_2 and/or alveolar collapse and/or the presence of alveoli filled with fluid, cells, debris, or blood); 2) compromised transition of oxygen from the alveoli to the blood (due to interstitial processes or pulmonary vascular disease); or 3) compromised ability of the blood to become oxygenated (due to obstructed blood flow, shunting, low Hgb concentration, or the presence of dysfunctional Hgb). The analysis of ABG values and calculation of the alveolar-arterial (A-a) gradient are important for the assessment of type I ARF.

Type II or "Hypercapnic" Respiratory Failure

Type II ARF ($PaCO_2 > 45$ mm Hg) represents the failure of the lungs to remove a sufficient amount of CO_2 and is characterized by decreased alveolar minute ventilation. An increase in $PaCO_2$ leads to hypoxemia because CO_2 displaces O_2 and effectively reduces the alveolar partial pressure of oxygen (PAO_2). In contrast to some cases of type I ARF,

FIGURE 9-1 ■ Compromised oxygenation of peripheral tissues may be the consequence of inadequate O_2 delivery or increased O_2 demand.

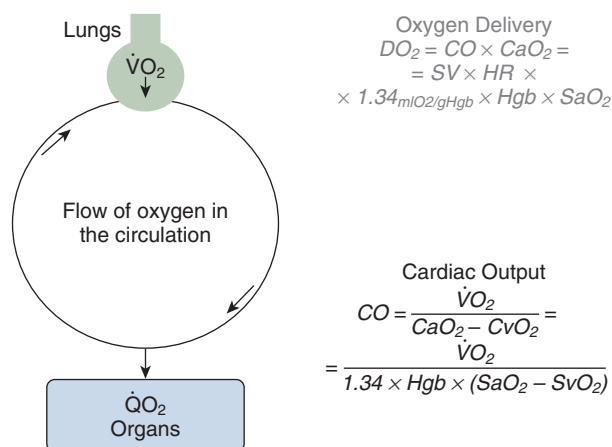

FIGURE 9-2 ■ The Fick principle establishes the relationship of O_2 uptake/consumption by peripheral tissues, cardiac output, and oxygen content in arterial and venous compartments ($\dot{V}O_2$, oxygen uptake; $\dot{Q}O_2$, oxygen consumption rate; DO_2 , oxygen delivery; CO , cardiac output; CaO_2 , arterial oxygen content; SV , stroke volume; HR , heart rate; Hgb , hemoglobin; SaO_2 , arterial oxygen saturation; SvO_2 , mixed venous oxygen saturation).

hypoxemia in type II ARF is easily corrected with supplemental oxygen. This type of respiratory failure is frequently due to acute or chronic neuromuscular dysfunction or the inability of the airways or lungs to ensure adequate ventilation and CO_2 exchange.

Type III or “Perioperative” Respiratory Failure

Type III respiratory failure is synonymous with perioperative respiratory failure and is related to atelectasis of the lung. It is often a consequence of abnormal abdominal and chest wall mechanics in the setting of surgery or trauma, especially with intrapleural or subdiaphragmatic pathologies. The patient usually splints the chest to limit involuntary movement of the injured region, leading to inadequate expansion of the dependent parts of the lungs, with resultant regional atelectasis and hypoventilation. As a result, type III ARF shares features with both type I (hypoxemic) and type II (hypercapnic) ARF. This type of ARF can be prevented or ameliorated by certain anesthetic strategies as well as perioperative measures such as elevating the head of the bed, early

TABLE 9-1 Pathophysiological Mechanisms That Lead to Hypoxia and Respiratory Insufficiency

- Extrapulmonary processes including chest wall and skeletal abnormalities (hypoxic hypoxia)
 - Deficiency of oxygen in inspired air (high altitude, suffocation)
 - Hypoactive hypoventilation (central nervous system trauma, drug toxicities, and neuromuscular and skeletal disorders)
 - Upper airway obstruction leading to hypoventilation (trauma and angioedema)
- Pulmonary etiologies (hypoxic hypoxia)
 - Hypoventilation caused by increased airway resistance (chronic obstructive pulmonary disease and asthma)
 - Abnormal alveolar ventilation-perfusion ratio (pulmonary embolism, pneumonia, aspiration, and emphysema)
 - Diminished diffusing capacity via the alveolar-capillary membrane (interstitial lung disease and pulmonary vascular disease)
 - Pulmonary shunting (atelectasis, pneumonia, hepatopulmonary syndrome, and arteriovenous malformations)
- Cardiac right-to-left shunts; e.g., atrial septal defect (hypoxic hypoxia)
- Inadequate capacity of blood to transport oxygen (anemic hypoxia)
 - Anemia
 - Hemoglobinopathies (methemoglobinemia and carbon monoxide poisoning)
- Inadequate oxygen transport due to a circulatory defect (static hypoxia)
 - General circulatory deficiency or collapse (shock or cardiac failure)
 - Localized circulatory deficiency (peripheral, cerebral, and coronary vessels)
- Abnormal tissue capability for using oxygen (histotoxic hypoxia)
 - Late-stage irreversible shock
 - Poisoning of cellular oxidation enzymes (cyanide or arsenic toxicity and heavy ethanol intoxication)
 - Diminished cellular metabolic capacity for using oxygen (severe vitamin deficiencies; e.g., beri-beri)

ambulation, incentive spirometry, avoiding excessive sedation, and lowering intraabdominal pressure.

Type IV or “High-demand” Respiratory Failure

Type IV respiratory failure is related to an inability of (normal or relatively normal lungs) to keep up with increased ventilatory demands associated with systemic hypermetabolism (e.g., secondary to sepsis). Under these conditions, respiratory muscle fatigue can lead to a

TABLE 9-2 Classification of Acute Respiratory Failure (Modified From¹⁰)

TABLE 9-3 Common Clues Obtained from the History, Symptoms, and Clinical Examination Findings That Can Help in the Initial Diagnostic Workup and Management of Acute Respiratory Failure

| HISTORY AND SYMPTOMS | SIGNS ON PHYSICAL EXAMINATION | DIAGNOSIS |
|--|---|--|
| Cough, sputum, secretions | Rales or wheezing | Pneumonia, chronic obstructive pulmonary disease (COPD) exacerbation, bronchiectasis |
| Sudden onset of shortness of breath | Normal auscultation and percussion, possible signs of leg swelling to suggest deep vein thrombosis | Pulmonary embolism |
| History of heavy smoking | Wheezing, rhonchi | Emphysema, chronic bronchitis |
| Orthopnea, chest pain, paroxysmal nocturnal dyspnea | Arrhythmia, peripheral edema, jugular venous distention, peripheral hypoperfusion | Congestive heart failure or acute coronary syndrome |
| Trauma, aspiration, blood transfusions | Diffuse crackles | Acute respiratory distress syndrome |
| History of allergies, wheezing or airway disease | Wheezing | Asthma, COPD |
| Exposure to heavy metals, handling of animals, dust or other significant environmental exposures | "Velcro" rales, clubbing | Chronic interstitial lung disease |
| Choking, aspiration, vomiting, dental procedures | Inspiratory stridor, poor air entry | Foreign body |
| Drug abuse | Constricted or dilated pupils, altered mental status, skin marks, perforated nasal septum, hypersalivation, decreased respiratory frequency | Central nervous system depression, intoxication |
| Exposure to a new drug/chemical or foods known to be allergenic | Swollen oral mucosa and tongue; stridor or wheezing | Angioedema, anaphylaxis |
| Progressive muscle weakness or immobility | Sensory abnormalities | Neuromuscular disorders |
| Trauma, procedures, inhalational injury | Absent breath sounds unilaterally, hypertympanic, tracheal deviation | Pneumothorax |
| Trauma, procedures | Absent breath sounds, dull on percussion, tracheal deviation | Hemothorax |

requirement for mechanical ventilation (MV) to support adequate minute ventilation.

■ DIAGNOSTIC WORK-UP

Obtaining a history is crucial in narrowing down the etiology of ARF. A focused physical examination also helps to assess the severity of respiratory failure and to determine the need for immediate interventions. Common signs include tachypnea, the use of accessory respiratory muscles, nasal flaring, abdominal paradoxical breathing, and retractions in the intercostal, suprasternal, or supraclavicular areas. One can also see irregular breathing patterns or poor chest wall excursion

in addition to cough, wheezing, copious secretions, or cyanosis. A detailed examination of the upper airway and chest, as well as a careful neurologic, cardiovascular, abdominal, skin, and musculoskeletal system examination, may also help to narrow the differential diagnosis. Table 9-3 lists common clues obtained from the history and physical examination of the patient, which can help to diagnose the etiology of respiratory failure.

Prior to the comprehensive diagnostic work-up, it is important to remember that a diagnostic procedure should not be a reason for delayed intervention in cases of severe ARF. ABG analysis should be obtained in all patients with suspected ARF. ABG helps to determine the chronicity of the respiratory failure and, more importantly, the

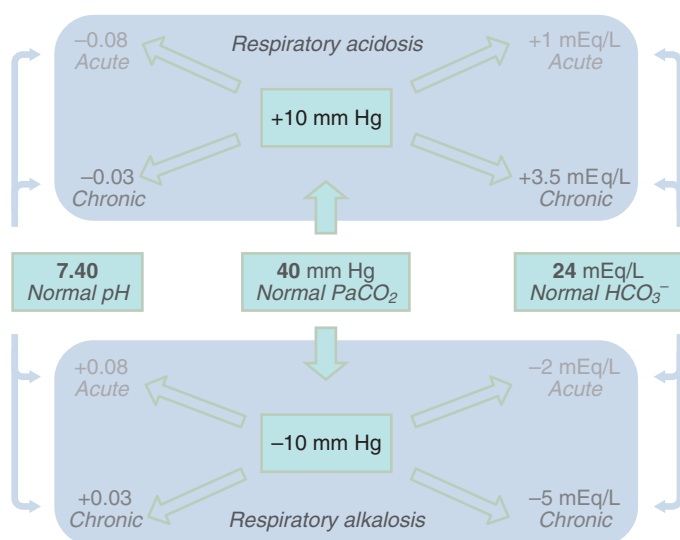

FIGURE 9-3 ■ Interpretation of an arterial blood gas in the setting of respiratory failure.

extent and severity of the ARF. Fig. 9-3 schematically displays the changes in ABG parameters in acute and chronic respiratory disorders. Laboratory work-up should also include complete blood count, basic metabolic profile, cardiac enzymes, and microbiological evaluation. Chest imaging, including computerized tomography when needed, can help with the diagnosis of a pulmonary pathology. Evaluating cardiac function with echocardiography can significantly narrow the diagnostic differential in patients with systemic disease and shock. With the increasing availability of the critical care bedside ultrasound, familiarization with the Rapid Ultrasound for Shock and Hypotension (RUSH) examination is recommended as a rapid tool for the assessment of patients with ARF.¹¹ Laryngoscopy or bronchoscopy may be necessary for the evaluation of airway patency in scenarios such as fixed obstruction, aspiration, foreign bodies, or severe secretions.

MANAGEMENT

Appropriate management of a patient with ARF usually requires admission to the ICU, where adequate support and close monitoring are available. Management should focus on both stabilization of the patient's ventilatory and hemodynamic status as well as correction of the pathophysiologic process underlying the respiratory failure. The "ABC" approach, which prioritizes airway, breathing, and circulation, has long been a basic tenet in the management of ARF.

Airway Patency

Securing airway patency is the first step in the management of ARF. This usually requires interventions such as positioning, the suctioning of secretions, treatment with bronchodilators, and/or the placement of an oral airway. When physical obstruction of the upper airway by a foreign body or mass is suspected, advanced invasive procedures, such as laryngoscopy or bronchoscopy, may be necessary. In cases of severe respiratory compromise that require more invasive ventilatory management, endotracheal intubation is indicated. This can be achieved via orotracheal or nasotracheal intubation or, in difficult cases when an endotracheal tube cannot be advanced through the vocal cords, emergency cricothyroidotomy. The inability of a patient to protect his or her airway because of compromised mental status (usually with a Glasgow Coma Scale score of <8) also warrants endotracheal intubation to secure the airway. The process of securing the airway in ARF requires an understanding of the ongoing pathologic process, as well as an advanced knowledge of the anatomy of the upper airway.

Breathing

Breathing assistance is required in both oxygenation and ventilation disorders. Treating hypoxemia should be the first step, which can be achieved with supplemental oxygen. Oxygen can be provided via nasal cannula, face mask, Venturi mask, nonrebreather mask, or high-flow oxygen delivery devices. When hypoxemia cannot be corrected with supplemental oxygen only, or ventilation is compromised, transition to MV may be necessary. MV may be provided via noninvasive positive pressure ventilation (NIPPV) or via invasive MV through an endotracheal tube. Severe respiratory failure with an inability to oxygenate and/or ventilate despite MV may occasionally require transition to extracorporeal membrane oxygenation (ECMO).¹²

Circulation

Normal breathing with negative pressure ventilation not only provides gas exchange but also affects hemodynamics on a breath-to-breath basis, helping to optimize venous return and cardiac output. Circulation affects our respiratory patterns, and they are also affected by ventilatory mechanics. Treating hypotension or hypertension and optimizing the cardiac output may help treat the underlying etiology of ARF and may also be necessary given the potential adverse effects of positive pressure ventilation on cardiac preload and afterload. In addition, anesthetics and sedatives used for mechanically ventilated patients, as well as paralytics used for intubation, have significant hemodynamic effects that should be anticipated and aggressively corrected as necessary.

Further Management and Monitoring

Along with focusing on the "ABC" of ARF, the treatment of its underlying cause is of paramount importance to the patient's outcome. Antibiotics and source control for the management of infections, cardiac or inotropic medications, revascularization, air or fluid evacuation, anticoagulation or thrombolysis, fluid expansion, diuretics, vasodilators, bronchodilators, glucocorticoids as well as many other medications and interventions may be required to treat the underlying etiology of ARF.

The success and adequacy of the management of ARF should be continuously monitored. Multiple blood gas analyses may be required to ensure that both oxygenation and ventilation are maintained within desired limits. In general, PaO₂ should be maintained at >55 to 60 mm Hg, a range that represents a threshold for severe hypoxemia. Arterial blood oxygen saturation (SpO₂) can be tested and correlated to PaO₂ and can be used as a surrogate marker for the adequacy of oxygenation with a general recommended goal of >88%. pH and PaCO₂ values reflect the adequacy of MV and are also useful in the setting of a metabolic acid-base disorder. ABG goals should in general be individualized. For example, permissive hypercapnia may be appropriate for some patients, whereas other patients may benefit from therapeutic hyperventilation.

MV

The purpose of MV is to improve oxygenation and ventilation while correcting respiratory acidosis and hypoxemia, meeting metabolic demands, resting respiratory muscles, and optimizing cardiac function and blood circulation. MV allows for augmented minute ventilation and the provision of high concentrations of oxygen and positive end expiratory pressure (PEEP). MV has also been shown to have a positive effect on gas exchange and the regional distribution of lung aeration and ventilation.¹³ MV can be *noninvasive*, involving a variety of interfaces such as nasal or face masks, or *invasive*, involving endotracheal intubation. General indications for intubation and invasive MV are described in Table 9-4.

Noninvasive positive pressure ventilation (NIPPV) has been increasingly utilized in the past two decades as an alternative to

TABLE 9-4 General Indications for Intubation and Mechanical Ventilation

| |
|--|
| Cardiorespiratory arrest or impending arrest |
| Respiratory distress/tachypnea with increased ventilatory demand and breathing effort leading to respiratory muscle fatigue |
| Severe hypercapnic respiratory failure with either poor candidacy for nasal intermittent positive pressure ventilation (NIPPV) or failure of NIPPV |
| Severe refractory hypoxemia with failure of noninvasive oxygen delivery devices |
| Severe refractory metabolic acid-base disorder |
| Inability to protect the airway |
| Inability to clear secretions |
| Need for therapeutic hyperventilation or hypoventilation |
| Upper airway obstruction with poor airway patency |
| Decreased respiratory drive with bradypnea |
| Coma with Glasgow Coma Scale score of <8 |
| Severe trauma |
| Surgery requiring general anesthesia |

endotracheal intubation and MV in appropriate clinical settings.¹⁴ NIPPV with continuous (CPAP) or bi-level positive airway pressure (BiPAP) modalities have been shown to be beneficial in selected cases of COPD exacerbation, cardiogenic pulmonary edema, obesity hypoventilation syndrome or decompensated obstructive sleep apnea, and neuromuscular disease.^{14,15} It has also been successfully used for respiratory failure in postoperative patients,¹⁶ immunocompromised patients,¹⁷ or in patients with a do-not-intubate (DNI) code status.¹⁸

NIPPV requires the patient's cooperation and an anatomically preserved upper airway. It is not a replacement for invasive MV and is not suitable for all patients with respiratory failure. Significantly depressed mental status, copious secretions with an inability to protect the airway, massive hemoptysis or hematemesis, recent upper gastrointestinal surgery or bowel obstruction, and cardiorespiratory arrest or severe arrhythmias are contraindications to its use.¹⁵ NIPPV is not widely recommended for use in advanced hypoxemic respiratory failure as its use may lead to a more difficult transition to MV in cases of NIPPV failure,¹⁹ although there is some evidence that it can be beneficial in the setting of severe hypoxemia during the process of transitioning to invasive MV.²⁰ Its use in shock states leading to type IV ARF may adversely affect venous return and pulmonary hemodynamics in volume-depleted patients.²¹

Invasive MV requires an endotracheal or tracheostomy tube as an interface between the patient and the ventilator. Prior to the initiation of invasive MV, a careful assessment of risks and benefits needs to be undertaken as both intubation and MV carry risks of potentially fatal complications. Though it is clearly a life-saving measure when appropriately utilized, invasive MV may lead to significant hemodynamic compromise that results from the sedative effects of medications used for intubation and MV, abrogation of the patient's inspiratory drive, and changes in cardiac preload, afterload, and interventricular dependence.^{22,23} MV also increases the risks of ventilator-associated lung

injury, dynamic hyperinflation, and ventilator-associated pneumonia, as well as discomfort due to patient-ventilator asynchrony. Importantly, in situations involving terminal illnesses or irreversible etiologies of ARF, a discussion with the patient and family regarding the appropriateness and expectations of invasive MV is warranted.

Evaluation of the patient's anatomy, such as the presence of facial hair; oral cavity inspection, including dentition, neck shape, and mobility; and the presence of secretions or obstruction, is helpful for predicting the odds of a difficult intubation and for planning of the specific intubation approach. Prior to intubation, the operator needs to carefully choose sedatives and anesthetics, secure vascular access and prepare hemodynamic support, and adequately pre-oxygenate the patient and prepare for supportive manual bag-valve mask ventilation.¹⁹ It is important to remember that every intubation in the setting of ARF may become a difficult intubation,²⁴ and experienced operators and rescue strategies for securing the airway need to be available. Upon endotracheal intubation, the tube position should be confirmed and secured to avoid accidental extubation.

While on a ventilator, the patient's comfort, gas exchange, mechanics, and ventilator waveforms need to be continuously monitored. The least amount of sedation required to achieve comfort and ventilator synchrony should be utilized.²⁵⁻²⁷ Spontaneous breathing trials should be initiated daily, once the patient's condition is stable.²⁷⁻²⁹ The patient's head should be elevated to >30°, and prophylaxis for deep venous thrombosis and peptic ulcer disease should be administered daily.

In patients with or at high risk for acute lung injury and acute respiratory distress syndrome (ARDS), a lung-protective ventilation strategy should be utilized. This entails low tidal volumes (~6 mL/kg of ideal body weight), permissive hypercapnia, and the maintenance of adequate static inspiratory or plateau pressures (<30 cm H₂O).^{30,31} Neuromuscular paralysis may be needed in cases of severe ARDS or ventilator dyssynchrony despite high doses of sedatives.³² In cases of refractory hypoxemia in severe ARDS, additional strategies,³³ including prone positioning,³⁴ pulmonary vasodilators (such as inhaled nitric oxide),³⁵ recruitment maneuvers,³⁶ high-frequency oscillatory ventilation,³⁷ or airway pressure release ventilation (APRV or bi-level ventilation),³⁸ have been utilized with variable success rates. Patients with profound nonresolving ARF despite the above mentioned strategies should be considered for ECMO if the underlying etiology is considered reversible.³⁹

CONCLUSION

ARF is one of the most common conditions encountered in the ICU and is associated with significant morbidity and mortality. Understanding the pathophysiology of ARF with regard to oxygen consumption, delivery, and transport; the etiologies of ARF (types I to IV); and the clinical presentation (acute or acute on chronic) is essential for the management of these patients. The priority in the management of ARF is to focus on the "ABC" approach, with efficient and effective decision making regarding the use of either NIPPV or invasive MV. Finally, therapies need to be directed at both the ARF itself as well as the underlying condition in order to optimize patient outcomes.

BACKGROUND AND EPIDEMIOLOGY OF PULMONARY EDEMA

Pulmonary edema (PE) is an emergency that demands immediate medical attention. PE is broadly classified into cardiogenic (increased hydrostatic pressure) or noncardiogenic (increased microvascular permeability) causes; however, it is common for critically ill patients to present with PE arising from a combination of cardiogenic and noncardiogenic etiologies. PE is a major health problem accounting for ~10% of intensive care unit (ICU) admissions¹ and associated with an estimated acute hospital mortality of ~10% to 25%²⁻⁴ and 1-year mortalities exceeding 40%.^{3,5,6}

PATHOPHYSIOLOGY OF PE

Normal pulmonary physiology favors a small net influx of fluid from the alveolar capillaries into the lung interstitial space (IS) that is facilitated by hydrostatic forces and by the presence of microscopic gaps between the capillary endothelial cells. The rate of fluid influx is mitigated by a protein osmotic pressure gradient favoring movement of fluid from the IS back into the circulating plasma. The resulting relatively small physiological fluid movement from the vasculature into the lungs is normally offset by fluid efflux from the lung IS via the pulmonary lymphatic system, which ultimately drains back into the systemic venous circulation. As fluid passes through the lung IS it is excluded from the alveolar space by occlusive tight junctions between alveolar epithelial cells.⁷ In the absence of acute lung injury (e.g., capillary damage), changes in the rate of fluid flux through the lungs are dictated primarily by changes in hydrostatic pressure. The pulmonary capillary wedge pressure (PCWP), derived from a pulmonary artery catheter balloon wedged into a pulmonary artery segment, is a reflection of left atrial filling pressure and is thought to most reliably estimate the hydrostatic pressure of the lung microcirculation.^{8,9}

The Starling equation for filtration mathematically represents the fluid balance between the pulmonary vasculature and IS, which “depends on the net difference in hydrostatic and protein osmotic pressures and permeability of the capillary membrane.”¹⁰

$$Q = K[(P_{mv} - P_{pmv}) - (\pi_{mv} - \pi_{pmv})]^9$$

where:

Q = net transvascular filtration of fluid into the IS

K = filtration coefficient

Ppmv = hydrostatic pressure in perimicrovascular IS

Pmv = hydrostatic pressure within the capillaries (e.g., the PCWP)

π_{mv} = protein osmotic pressure in the circulation

π_{pmv} = protein osmotic pressure in the perimicrovascular IS

While the Starling equation is useful in understanding the mechanisms favoring PE formation, it is impractical to accurately measure most of these parameters clinically. Nonetheless, a basic understanding of this equation is helpful to clinicians caring for patients with PE.

Cardiogenic PE (Increased Hydrostatic Pressure)

Increased hydrostatic pressure in the pulmonary capillaries results in increased transvascular fluid filtration and is most often caused by

volume overload or impaired left ventricular function resulting in elevated pulmonary vascular pressures. Mild elevations of left atrial pressure reflected by PCWPs of 18–25 mm Hg cause edema formation in the perimicrovascular and peribronchovascular IS. As left atrial pressure rises further (PCWP > 25 mm Hg), the capacitance of the lymphatics and IS (estimated at ~500 mL fluid)⁹ is exceeded and fluid overwhelms the lung epithelial barrier, flooding the alveoli with protein-poor fluid.^{9,11} Hypoxemia results clinically due to the development of alveolar fluid accumulation, destabilization of alveolar units (impaired surfactant function), and consequent ventilation-perfusion (V/Q) mismatching.

Noncardiogenic PE (Increased Vascular Permeability)

Noncardiogenic PE refers to any condition promoting abnormal increases in the vascular permeability of the lung, thereby promoting greater fluid and protein flux into the lung IS and air spaces. In terms of the Starling equation, pulmonary vascular damage equates with an increase in the filtration coefficient and an increase in the protein osmotic pressure in the lung IS, both of which favor lung edema formation. Another factor contributing to impaired gas exchange during noncardiogenic PE relates to the disruption of the alveolar epithelial barrier, such as occurs when lung IS pressure is severe enough to disrupt tight junctions, or when direct inflammatory or toxic injury to the epithelial lining of the alveoli occurs. Damaged alveolar epithelium has a reduced capacity for the active transport of fluid from the alveolar space into the lung IS and causes impaired surfactant production (reduced surface activity) favoring alveolar collapse during normal tidal breathing. Examples of direct injury to the alveolar epithelium include gastric aspiration or pneumonia. Conditions that promote acute lung capillary endothelial injury include systemic infections (sepsis), severe burns, trauma, and other systemic inflammatory conditions. Injury to the lung capillary endothelium and/or alveolar epithelium is the hallmark of acute lung injury (ALI) and acute respiratory distress syndrome (ARDS), which represent a spectrum of progressive noncardiogenic lung injury associated with impaired gas exchange (shunting, V/Q mismatching) and reduced lung compliance (increased work of breathing).^{9,11}

ESTABLISHING THE ETIOLOGY OF PE IN THE CLINICAL SETTING

It is important for care providers to quickly establish the cause of acute PE such that appropriate therapy can be rapidly initiated to avoid serious, life-threatening complications. For instance, a patient with an acute rupture of mitral valve *chordea tendineae* would benefit from afterload reduction (e.g., peripheral vasodilators, intraaortic balloon pump [IABP]), and immediate mitral valve surgery,¹² whereas a patient with ARDS related to sepsis would benefit from high concentrations of inspired oxygen, positive pressure ventilation, and early antibiotics. Unfortunately, the cause of PE can be difficult to establish in the critical care setting and requires a skilled clinician with appropriate diagnostic tools.

Common clinical manifestations of PE (of any cause) include the acute onset of dyspnea, anxiety, orthopnea, and in some cases pink (blood-tinged) frothy sputum. On examination, patients have signs of

increased sympathetic tone (tachycardia, hypertension), increased work of breathing (e.g., accessory muscle use and diaphoresis), inspiratory crackles of the lung, and peripheral cyanosis.

Clinical Features Favoring Cardiogenic PE

Beyond the clinical features of PE previously mentioned, historical information, such as a recent myocardial infarction, new onset of cardiac arrhythmias, and exam findings of elevated jugular venous pressures, a third heart sound (S3), new murmurs, and/or dependent edema would favor the diagnosis of cardiogenic over noncardiogenic PE. CXR findings of cardiomegaly, a centralized pattern of interstitial and alveolar opacities, and/or the presence of pleural effusions further support the diagnosis of cardiogenic PE.¹³ Other supporting evidence includes elevated brain natriuretic peptide (BNP > 1200 pg/mL), or troponin, a marker of acute myocardial injury. However, these biomarkers lack diagnostic specificity.¹⁴ Cardiac imaging, particularly echocardiography, is very useful diagnostically, and is shown to alter the management of a high percentage of critically ill patients presenting with acute PE.^{15,16} The use of invasive means to measure left ventricular filling pressures may be useful in complex cases (e.g., treatment-refractory PE)¹⁷ but has been largely replaced by less invasive approaches (e.g., central venous pressure [CVP] monitoring, transpulmonary thermodilution).¹⁷⁻¹⁹

Clinical Features Favoring Noncardiogenic PE

ALI and ARDS encompass a spectrum of moderate to severe gas exchange abnormalities developing consequent to altered pulmonary vascular permeability, which is often further complicated by alveolar epithelial damage. The differential diagnosis of ALI/ARDS is broadly categorized as processes causing direct versus indirect lung injury (Box 10-1), the most common direct causes being severe pulmonary infections and gastric aspiration pneumonia, whereas severe infections (sepsis), multiple transfusions, and trauma are common causes of indirect ALI.

Highly specific diagnostic tests for ALI/ARDS are lacking, and the differentiation of ALI/ARDS from cardiogenic PE largely relies on the clinical acumen of the critical care providers. In this regard, details of the present illness as it relates to the known risk factors for ALI often provide important clues (see Box 10-1), and certain objective examination and test results (e.g., BNP < 200 pg/mL)¹⁴ support the diagnosis of ALI/ARDS (Table 10-1).

Certain causes of noncardiogenic PE deserve special consideration because of their unique clinical presentations.

Neurogenic PE

It occurs following a significant central nervous system insult²⁰ and is most often triggered by conditions associated with rapid and extreme elevations in intracranial pressure (ICP)^{20,21} as well as in the setting of acute spinal cord injury, intracranial hemorrhage, or during status epilepticus. Sympathetic nervous system activation and catecholamine release are primary mechanisms.²² The condition typically resolves within 48 hours of ICP normalization.^{20,23}

Transfusion-Related Acute Lung Injury (TRALI)

It is an adverse response to transfusion of blood products containing plasma characterized by the acute (within 6 hours) onset of dyspnea, hypoxemia, and bilateral pulmonary infiltrates that is mediated mechanistically by anti-HLA antibodies, neutrophil activation, and related endothelial barrier damage.^{24,25} The diagnosis of TRALI is made

BOX 10-1

Common Causes of Cardiogenic and Noncardiogenic Pulmonary Edema

CARDIOGENIC PULMONARY EDEMA

- Acute exacerbation of heart failure
- Acute valve dysfunction (e.g., mitral valve chordae tendineae rupture)
- Arrhythmia/Myocardial infarction
- Hypertensive crisis
- Fluid overload following aggressive volume resuscitation (e.g., postoperative)
- Ventricular septal rupture
- Pericardial tamponade

NONCARDIOGENIC PULMONARY EDEMA

- Direct lung injury
 - Pneumonia
 - Gastric aspiration
 - Toxic inhalation
 - Negative pressure related (e.g., strangulation)
- Indirect causes of lung injury
 - Sepsis
 - Trauma
 - Pancreatitis
 - Multiple blood transfusions
 - Burn injury

TABLE 10-1 Distinguishing Cardiogenic and Noncardiogenic Pulmonary Edema

| | HISTORY | EXAM | LABS | IMAGING | PULMONARY ARTERY CATHETER |
|----------------|--|--|---|---|---|
| Cardiogenic | Heart disease Renal disease Uncontrolled HTN Edema Orthopnea Recent administration of IV fluids or blood products | Heart failure exam findings: Distended neck veins S3 heart sound Dependent edema Elevated blood pressure Cool extremities | *↑BNP > 1200 pg/mL ↑Creatinine (in setting of volume overload) ↑↑Troponin | CXR: CMG Pleural effusions #Kerley B lines TEE: ↓LVEF Diastolic filling defect Severe mitral or aortic valvular disease Pericardial effusion with tamponade VSD | PCWP > 18 mm Hg Prominent V-waves (mitral regurgitation) Elevation and equilibration of right atrial pressure, pulmonary artery diastolic and PCWP (tamponade physiology) CVP > 12 mm Hg |
| Noncardiogenic | Sepsis Aspiration event Trauma (long bone fractures) Burn injury Pancreatitis Multiple transfusions | Signs of active infection Extensive burn injury Evidence of trauma (absence of heart failure exam findings) | ↑WBC *BNP < 200 pg/mL | CXR: Diffuse central and peripheral infiltrates Normal heart size No or minimal pleural effusions TEE: Normal LV and valvular function No evidence of volume overload | PCWP < 18 mm Hg CVP < 12 mm Hg |

clinically and by the exclusion of cardiogenic edema or fluid overload. Thus, a low BNP (<250 pg/mL) supports the diagnosis.²⁶ Treatment includes immediate discontinuation of any transfusing blood products and supportive care, which often requires intubation and mechanical ventilation. Duration of symptoms is typically limited (48–96 hours).²⁵

Re-expansion Pulmonary Edema

It typically occurs within hours of draining a large pleural effusion in cases of sustained (>72 hours) lung collapse. Associated symptoms range from mild to life-threatening, including dyspnea, cough with frothy sputum production, chest discomfort, and hypoxemic respiratory failure. A unilateral edema pattern of the re-expanded lung is typical on CXR but occasionally can occur in the contralateral lung or in both lungs.^{27,28} Most patients completely recover with supportive care within a few days. Preventative strategies include discontinuation of pleural fluid removal at the onset of any signs of chest discomfort, limiting volume removal to <1.5 L, and avoidance of high negative pressure (less than −20 cm H₂O).²⁹

Negative Pressure PE (NPPE)

It rarely presents in the immediate postextubation period following the acute development of negative intrathoracic pressure generated during respiratory efforts against an obstructed upper airway. NPPE occurs in less than 0.1% of all elective surgeries and is most common in young, healthy and athletic patients during postextubation laryngospasm. Other causes of NPPE include strangulation (or hanging), severe sleep apnea, endotracheal tube occlusion, or epiglottitis.³⁰ As with re-expansion PE, the condition typically resolves within several days.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF PULMONARY EDEMA

Table 10-1 summarizes the typical clinical findings that distinguish cardiogenic from noncardiogenic PE. Ironically, pulmonary artery (PA) catheterization, the most definitive diagnostic modality, is no longer routinely used because of frequent complications (e.g., bleeding,

pneumothorax, arrhythmias, infections, vessel trauma) and its unreliability due to improper calibration or misinterpretation of the data.^{31–33} Thus, less invasive techniques have largely replaced PA catheters for the routine evaluation of cardiogenic causes of PE in the ICU setting.

Transesophageal echocardiography (TEE) is the most widely used tool for the evaluation of critically ill patients with suspected cardiac disease. In the context of PE, TEE can rapidly detect serious cardiac diseases associated with elevated left ventricular filling pressures, including impaired left ventricular ejection fraction due to ischemic (typically causing regional wall motion abnormalities) or nonischemic (diffuse wall motion abnormalities) muscle disease, significant valvular disease, or pericardial effusions causing tamponade physiology.³⁴

Two alternative modalities have emerged to evaluate PE. The pulse indicator continuous cardiac output (PiCCO) system estimates the pulmonary vascular permeability index in critically ill patients.³⁵ Quantitative computed tomography (QCT) analysis with single-indicator thermodilution has also been used to detect PE in the setting of ARDS.³⁶ To date, no study has shown superiority of PiCCO or QCT compared to conventional approaches (e.g., CVP-guided) for PE assessment in the context of ARDS.^{36,37}

MANAGEMENT OF PE

Therapeutic approaches are classified as either cardiovascular or pulmonary interventions. Cardiovascular interventions aim to reduce transcapillary fluid flux into the lung by reducing pulmonary capillary pressures. As shown in Fig. 10-1 and Box 10-2, such interventions aim to reduce preload (e.g., loop diuretics, nitrates, or ultrafiltration in renal failure), reduce afterload (systemic vasodilating agents including nitrates, angiotensin converting enzyme [ACE] inhibitors, phosphodiesterase inhibitors), or optimize cardiac contractility during impaired left ventricular function (catecholamines, phosphodiesterase [PDE] inhibitors, intraaortic balloon pump). Although most effective in the setting of cardiogenic PE, pulmonary capillary hydrostatic pressure reduction can also mitigate the severity of PE during noncardiogenic PE.

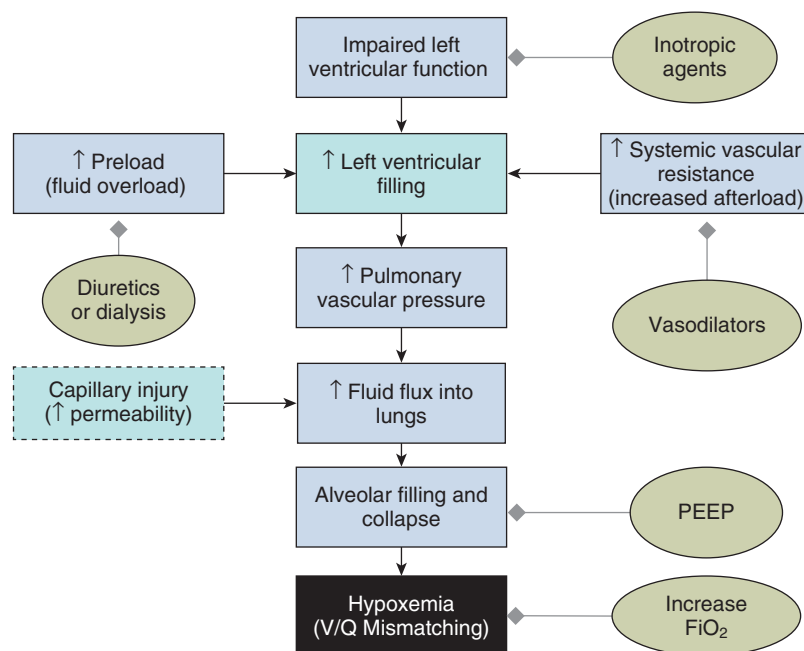

FIGURE 10-1 ■ Acute management of pulmonary edema. This schematic represents basic mechanisms distinguishing cardiogenic and noncardiogenic pulmonary edema (red boxes) and the contributing factors (blue boxes) that ultimately lead to impaired gas exchange (black box). The green circles represent treatments that are available in the intensive care unit setting to reduce pulmonary edema or to mitigate its adverse consequences.

BOX 10-2**Management of Cardiogenic Pulmonary Edema****DECREASE PRELOAD**

- Diuretics (e.g., furosemide): decrease systemic venous tone and extracellular volume/volume overload⁶
- Opiates (e.g., morphine sulfate): reduces sympathetic tone.
- Nitrates (e.g., nitroglycerin): venous and arterial vasodilator,³¹ reduces myocardial oxygen demand⁴²
- Nesiritide: recombinant BNP that results in vasodilation and diuresis³¹
- Ultrafiltration (volume removal)

AFTERLOAD REDUCTION

- ACE inhibitor/ARB: reduce preload and afterload^{42,43}
- Nitroprusside (decreases venous return and afterload)
- Intraaortic balloon pump

INOTROPIC SUPPORT

- Dobutamine
- Dopamine
- Phosphodiesterase inhibitors (e.g., milrinone)
- Vasopressin (e.g., tolvaftan)

Pulmonary interventions are designed to optimize gas exchange, particularly oxygenation, by recruiting unstable, collapsed or fluid-filled alveolar units primarily through the administration of positive end expiratory pressure (PEEP). PEEP, typically 5-15 cm H₂O, counteracts alveolar collapse during the ventilator cycle to enhance V/Q matching and consequently oxygen diffusion from the alveoli to the blood. Alveolar stabilization also reduces the work of breathing by improving CO₂ exchange (i.e., lower ventilatory rates) and lung compliance. In addition to PEEP, it is often necessary to increase the fractional inspired oxygen concentration (Fio₂) to maintain adequate oxygenation (see Fig. 10-1). PEEP may be provided by a tight-fitting, occlusive face mask in the form of continuous positive airway pressure (CPAP) or by noninvasive positive pressure ventilation (NIPPV) wherein inspiratory support is added to PEEP (bilevel ventilation). Positive pressure ventilation further mitigates cardiogenic PE by decreasing both preload and afterload.⁹ Early use of NIPPV for respiratory distress in cardiogenic PE should be strongly considered as it provides support while awaiting the benefits of the aforementioned medical interventions. NIPPV has been shown to reduce both the need for endotracheal intubation and early mortality, as well as decrease

ICU length of stay.³⁸ NIPPV is a helpful adjunct to medical therapy; however, it is unclear if bilevel NIPPV is superior to CPAP in improving dyspnea, work of breathing, oxygenation, and Paco₂ retention.^{39,40} Endotracheal intubation and sedation may be required for patients with intolerably high work of breathing or altered mental status.

When ventilator support is required in the setting of noncardiogenic PE, a lung-protective ventilation strategy using lower tidal volumes (6 mL/kg ideal body weight or less) is highly recommended to minimize lung injury and PE severity.⁴¹

KEY POINTS

1. Pulmonary edema is broadly classified into cardiogenic (increased hydrostatic pressure) or noncardiogenic (increased microvascular permeability) causes; however, it is common for critically ill patients to present with pulmonary edema arising from a combination of cardiogenic and noncardiogenic etiologies.
2. Common clinical manifestations of pulmonary edema (of any cause) include the acute onset of dyspnea, anxiety, orthopnea, and in some cases pink (blood-tinged) frothy sputum. On examination, patients have signs of increased sympathetic tone (tachycardia, hypertension), increased work of breathing (e.g., accessory muscle use and diaphoresis), inspiratory crackles of the lung, and peripheral cyanosis.
3. In addition to the history and physical exam, laboratory testing (troponin, BNP) and imaging (CXR, echocardiogram) may be helpful in differentiating between cardiogenic and noncardiogenic causes of the pulmonary edema.
4. Management should be directed at the cause(s) of the pulmonary edema. In addition, early use of NIPPV for respiratory distress in cardiogenic PE should be strongly considered because it provides support while awaiting the benefits of the medical interventions described above.

Although polyuria in critically ill patients is less common than oliguria, it is an important manifestation of a number of important clinical conditions. Unless it is recognized and appropriately managed, polyuria can rapidly lead to the development of intravascular volume depletion and/or severe hyponatremia. Generally, urine flow varies depending on fluid intake, insensible losses (e.g., perspiration), and renal function. The average person excretes about 600 to 800 mOsm of solutes per day, and average urine output is about 1.5 to 2.5 L/day.

Polyuria has been variably defined in the literature. The most commonly used definition is entirely based upon the absolute urine volume and arbitrarily defines polyuria as a urine volume of more than 3 L/day. However, some authors prefer to define polyuria as “inappropriately high urine volume in relation to the prevailing pathophysiologic state,” regardless of the actual volume of urine.^{1,2}

■ CLASSIFICATION

Polyuria is broadly classified into *water diuresis* or *solute diuresis*, depending upon whether water or solute is the primary driving force for the increased urine output. However, some patients have mixed water and solute diuresis.

Water Diuresis

Definition and Pathophysiology

If urine output is greater than 3 L/day, and the urine is dilute (urine osmolality < 250 mOsm/L), total solute excretion is relatively normal, and polyuria occurs due to the excessive excretion of water. In general, diuresis is marked, and urine osmolality (Uosm) is often less than 100 mOsm/L. Water diuresis is usually secondary to excess water intake (as in primary polydipsia) or inability of the renal tubules to reabsorb free water, as in central or nephrogenic diabetes insipidus (DI). A good understanding of water homeostasis is critical for recognizing and managing water diuresis.

The normal plasma osmolality is 275 to 285 mOsm/L. To maintain this steady state, water intake must equal water excretion. The primary stimulus for water ingestion is thirst, mediated either by an increase in effective osmolality or a decrease in blood pressure or effective circulating volume. Under normal circumstances, water intake generally exceeds physiologic requirements.

Unlike water intake, water excretion is very tightly regulated by multiple factors. The most dominant regulating factor affecting water excretion is arginine vasopressin (AVP), a polypeptide synthesized in the hypothalamus and secreted by the posterior pituitary gland. Once released, AVP binds to vasopressin-2 (V2) receptors located on the basolateral membranes of renal epithelial cells lining the collecting ducts. Binding of AVP to V2 receptors initiates a sequence of cellular events, ultimately resulting in the insertion of water channels into the luminal cell membrane. The presence of these water channels permits passive diffusion of water (hence its reabsorption) across the collecting duct. Any derangement in this process results in a lack of or inadequate water reabsorption by the collecting duct, resulting in water diuresis. The major stimulus for AVP release is plasma hypertonicity. AVP release is also affected by other nonosmotic factors, such as the effective circulating volume, hypoglycemia, and drugs. In summary, water diuresis occurs either because of excessive water intake sufficient to

overwhelm the renal excretory capacity (primary polydipsia) or the impairment of renal water reabsorption itself (central or nephrogenic DI). Impaired renal water reabsorptive capacity (leading to water diuresis) in turn can occur either as a result of failure of AVP release in response to normal physiologic stimuli (central or neurogenic DI) or failure of the kidney to respond to AVP (nephrogenic DI). In most patients, the degree of polyuria is primarily determined by the degree of AVP deficiency or AVP resistance.

Primary Polydipsia

Primary polydipsia can be clinically recognized based on the history of the patient. Usually there is a history of psychiatric illness along with a history of excessive water intake. Many patients with chronic psychiatric illnesses have a moderate to marked increase in water intake (up to 40 L/day).^{3,4} It is presumed that a central defect in thirst regulation plays an important role in the pathogenesis of primary polydipsia. In some cases, the osmotic threshold for thirst is reduced below the threshold for the release of AVP. The mechanism responsible for abnormal thirst regulation in this setting is unclear. There is evidence that these patients have other defects in central neurohumoral control as well.⁵ Hyponatremia, when present, also points to the diagnosis of primary polydipsia. The diagnosis of primary polydipsia is usually evident from low urine and plasma osmolalities in the face of polyuria. Hypothalamic diseases such as sarcoidosis, trauma, and certain drugs, (e.g., phenothiazines) can lead to primary polydipsia (Table 11-1). There is no proven specific therapy for psychogenic polydipsia. Free water restriction is the mainstay of therapy.

Central Diabetes Insipidus

Inadequate secretion of AVP (central DI) can be caused by a large number of disorders that act at one or more of the sites involved in AVP secretion, interfering with the physiologic chain of events that lead to the release of this hormone. However, the most common causes of central DI account for the vast majority of cases. These common causes include neurosurgery, head trauma, brain death, primary or secondary tumors of the hypothalamus, and infiltrative diseases such as Langerhans cell histiocytosis (see Table 11-1).

Nephrogenic Diabetes Insipidus

Nephrogenic DI refers to a decrease in urinary concentrating ability due to renal resistance to the action of AVP. In some cases, collecting duct cells fail to respond to AVP. Other factors that can cause renal resistance to AVP are problems that interfere with the renal counter-current concentrating mechanism, such as medullary injury or decreased sodium chloride reabsorption in the medullary aspect of the thick ascending limb of the loop of Henle. In children, nephrogenic DI is usually hereditary. Congenital or hereditary nephrogenic DI is an X-linked recessive disorder resulting from mutations in the V2 AVP receptor gene.⁶ The X-linked inheritance pattern means that males tend to have marked polyuria. Female carriers are usually asymptomatic but occasionally have severe polyuria. In addition, different mutations are associated with different degrees of AVP resistance. Nephrogenic DI can also be inherited as an autosomal recessive disorder due to mutations in the aquaporin gene that result in absent or defective water channels, thereby causing resistance to the action of AVP.⁷

TABLE 11-1 Causes of Polyuria

1. Polyuria secondary to water diuresis
 - a. Excessive intake of water
 - i. Psychogenic polydipsia
 - ii. Drugs—anticholinergic drugs, thioridazine
 - iii. Hypothalamic diseases—trauma, sarcoidosis
 - b. Defective water reabsorption by the kidney
 - i. Central diabetes insipidus (vasopressin deficiency)
 - ii. Renal tubular resistance to AVP
2. Congenital nephrogenic diabetes insipidus
3. Acquired nephrogenic diabetes insipidus
 - a. Hypercalcemia
 - b. Hypokalemia
 - c. Drugs—lithium, demeclocycline
 - d. Chronic renal diseases—postobstructive diuresis, polyuric phase of ATN
 - e. Other systemic diseases—amyloidosis, sickle cell anemia
4. Polyuria secondary to solute diuresis
 - a. Electrolyte-induced solute diuresis
 - i. Iatrogenic—excessive sodium chloride load, loop diuretic use
 - ii. Salt-wasting nephropathy (rarely causes polyuria)
 - b. Nonelectrolyte solute-induced diuresis
 - i. Glucosuria—diabetic ketoacidosis, hyperosmolar coma
 - ii. Urea diuresis—high-protein diet, ATN
 - iii. Iatrogenic—mannitol

ATN, acute tubular necrosis; AVP, arginine vasopressin.

The most common cause of nephrogenic DI in adults is chronic lithium ingestion (see Table 11-1). Polyuria occurs in about 20% to 30% of patients on chronic lithium therapy. The impairment in the nephron's concentrating ability is thought to be due to decreased density of V2 receptors or decreased expression of aquaporin-2, a water channel protein. Other secondary causes of nephrogenic DI include hypercalcemia, hypokalemia, sickle cell disease, and other drugs (see Table 11-1). Water diuresis can also follow relief of obstructive nephropathy. Hypercalcemia-induced nephrogenic DI occurs when the plasma calcium concentration is persistently above 11 mg/dL (2.75 mmol/L). This defect is generally reversible with correction of hypercalcemia. The mechanism(s) responsible for hypercalcemia-induced nephrogenic DI remain incompletely understood. Compared to hypercalcemia-induced DI, hypokalemia-induced nephrogenic DI is less severe and often asymptomatic. A rare form of nephrogenic DI can occur during the second half of pregnancy (gestational DI). This condition is thought to be caused by release of a vasopressinase from the placenta, leading to rapid degradation of endogenous or exogenous AVP.⁸

Approach to Hypotonic Polyuria (Water Diuresis)

The accurate diagnosis of hypotonic polyuria is often indicated by the plasma sodium concentration and the patient history. When the problem is primary polydipsia, the plasma sodium concentration is usually low (dilutional hyponatremia), whereas when the problem is central or nephrogenic DI, the plasma sodium concentration is typically normal or high (due to the loss of solute-free water in excess of solutes). The rate of onset of polyuria can sometimes provide a clue about the diagnosis; when central DI is the problem, the onset of polyuria is generally abrupt, whereas when nephrogenic DI or primary polydipsia is the problem, the onset of polyuria tends to be more gradual. When the diagnosis of central versus nephrogenic DI is unclear, the diagnosis can be confirmed by determining the urinary response to an acute increase in plasma osmolality induced either by water restriction or, less commonly, by administration of hypertonic saline (Fig. 11-1).

Comparing urinary osmolality after dehydration with that after vasopressin administration can help differentiate DI due to vasopressin deficiency from other causes of water diuresis (see Fig. 11-1). In this test, fluids are withheld long enough to result in stable hourly urinary osmolality values (<30 mmol/kg rise in urine osmolality for 3 consecu-

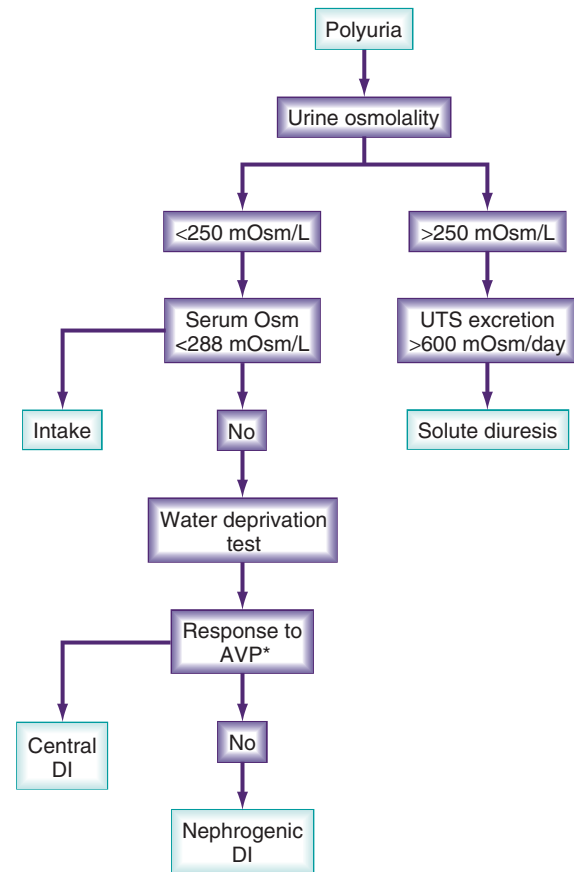

FIGURE 11-1 ■ Approach to polyuria. *Response to AVP is defined as a greater than 9% increase in urine osmolality between 30 and 60 minutes after vasopressin administration (see text for details). AVP, arginine vasopressin; DI, diabetes insipidus; UTS, urine total solute concentration.

tive hours). Plasma osmolality and urine osmolality are measured at this time point, and then the patient is intravenously (IV) administered 5 units of aqueous vasopressin. The clinician subsequently measures the osmolality of a urine sample collected during the interval from 30 to 60 minutes after the administration of vasopressin. In subjects with normal pituitary function, urinary osmolality does not rise by more than 9% after vasopressin injection. However, in central DI, the increase in urine osmolality after vasopressin administration exceeds 9%. To ensure the adequacy of dehydration, plasma osmolality prior to vasopressin administration should be greater than 288 mmol/kg. There is little or no increase in urine osmolality with dehydration in patients with nephrogenic DI, and there is no further change after vasopressin injection. In the future, a novel method to confirm the results of the water restriction test will be to measure the urinary excretion of aquaporin-2, the collecting tubule water channel that normally fuses with the luminal membrane of the collecting tubule cells under the influence of AVP. In one study, urinary aquaporin-2 excretion substantially increased to a comparable extent after the administration of vasopressin in normal subjects and in those with central DI.⁹ However, in patients with hereditary nephrogenic DI, urinary aquaporin-2 excretion was unchanged after vasopressin administration.

Treatment of Water Diuresis

Central diabetes insipidus can be treated by replacing AVP. The agent of choice is desmopressin, since it has prolonged antidiuretic activity and a very minimal vasopressor effect. It is usually administered intranasally at doses of 10 to 20 µg once or twice a day. Patients with central

DI with some residual releasable AVP can be treated with drugs, such as carbamazepine (100 to 300 mg twice daily), clofibrate (500 mg every 6 hours), or chlorpropamide (125 to 250 mg once or twice a day), that stimulate AVP release.

Primary polydipsia can only be treated by eliminating the underlying cause. In patients with schizophrenia and polydipsia, clozapine has been shown to have a beneficial effect.

The mainstay of treatment of nephrogenic DI is solute restriction and diuretics. Thiazide diuretics in combination with a low-salt diet can diminish the degree of polyuria in patients with persistent and symptomatic nephrogenic DI. Thiazide diuretics (e.g., hydrochlorothiazide) act by inducing mild volume depletion. Hypovolemia induces an increase in proximal sodium and water reabsorption, thereby diminishing water delivery to AVP-sensitive sites in the collecting tubules and reducing the urine output. The potassium-sparing diuretic, amiloride, also may be helpful.¹⁰

Solute Diuresis

Solute diuresis causing polyuria is due to solute excretion in excess of the usual excretory rate.¹¹ Total daily urinary solute excretion widely varies among different ethnicities, cultures, and dietary habits. The average urinary solute excretion in a healthy American adult is between 500 and 1000 mOsm/d. Solute diuresis can be very severe and can be caused by more than one solute concurrently. Solute diuresis is a relatively common clinical condition and one with important clinical implications. Unless there is an adequate replacement of solute and water, a persistent solute diuresis contracts extracellular volume, leading to severe dehydration and hypernatremia. Although glucosuria is the major cause of an osmotic diuresis in outpatients, other conditions are often responsible when polyuria develops in the hospital. These conditions include administration of a high-protein diet, in which case urea acts as the osmotic agent, and volume expansion due to saline loading or the release of bilateral urinary tract obstruction. Multiplying urine osmolality by the 24-hour urine volume gives an estimate of total urine solute concentration. If urinary total solute concentration is abnormally large, a solute diuresis is present.

Solute diuresis can be due to either excessive electrolyte excretion or excessive nonelectrolyte solute excretion. If the total urinary elec-

trolyte excretion exceeds 600 mOsm/d, then an electrolyte diuresis is present. The total urinary electrolyte excretion (in mOsm/d) can be estimated as $2 \times (\text{urine } [\text{Na}^+] + \text{urine } [\text{K}^+]) \times \text{total urine volume}$.^{1,12}

Electrolyte diuresis is usually driven by a sodium salt, usually sodium chloride (NaCl).¹³ Common causes of NaCl-induced diureses are iatrogenic administration of excessive normal saline solution, excessive salt ingestion, and repetitive administration of loop diuretics. Most often, NaCl-induced diuresis is accompanied by water diuresis, causing a mixed solute-water diuresis. Also, more than one electrolyte may be responsible for the diuresis.

A clearly excessive value for urine nonelectrolyte excretion (i.e., >600 mOsm/d) implies that nonelectrolytes are the predominant solutes contributing to the diuresis. The urinary nonelectrolyte excretion can be calculated by subtracting urine electrolyte excretion from the total urine solute excretion. The urine osmolality in these disorders is usually above 300 mOsm/kg, the high osmolality contrasting with the dilute urine typically found with a water diuresis. Furthermore, total solute excretion (calculated as the product of urine osmolality and the urine output over a 24-hour urine collection period) is normal with a water diuresis (600 to 900 mOsm/d) but markedly increased with an osmotic diuresis. The most common nonelectrolyte solute causing excessive diuresis is glucose. Conditions associated with glucose-induced diuresis include diabetic ketoacidosis or hyperosmolar coma.¹⁴ Excessive excretion of urea is another important cause of solute diuresis. This problem can occur following relief of urinary tract obstruction, as a consequence of enteral nutrition using a high-protein tube feeding formula, or during recovery from acute tubular necrosis.¹⁵ Mannitol administration (e.g., as a therapy for intracranial hypertension) also can lead to significant solute diuresis. This issue is pertinent because mannitol is often administered to patients with head trauma, who are at risk for development of nephrogenic DI. The correct diagnosis of solute diuresis depends on a clear systematic approach (see Fig. 11-1). Management usually involves treatment of the underlying disorder and repletion of extracellular volume by hydration. Since solute diuresis is often accompanied by hypernatremia, and very rapid correction of hypernatremia can have disastrous consequences (e.g., cerebral herniation), it is crucial to carefully monitor serum Na^+ . The serum Na^+ should not be permitted to decrease more than 0.5 to 1 mEq/L per hour.

Oliguria is an exceedingly common diagnostic problem faced on a daily basis by the critical care practitioner. The goal of this chapter is to provide a practical, physiology-based approach to diagnosing and treating oliguria.

DEFINITIONS AND EPIDEMIOLOGY

A number of definitions for oliguria can be found in the literature. An average person excretes 600 mOsm of solute/day. The maximal urinary concentration that can be achieved, however, is 1200 mOsm/L. Hence a urine output of at least 500 mL per day is obligatory for excreting the daily solute load. Therefore oliguria has generally been defined as urine output less than 500 mL per 24 hours. In order to standardize the use of the term across different studies and populations, the Acute Dialysis Quality Initiative (ADQI) adopted a definition of *oliguria* as urine output of less than 0.3 mL/kg/h for at least 24 hours (www.ADQI.org). For all practical purposes, however, urine output under 0.5 mL/kg/h is usually considered inadequate for most critically ill patients. This is in part because fluid input due to medications, nutrition, and other reasons typically exceeds this threshold in critically ill patients, and fluid overload may result if urine output is inadequate to maintain fluid balance.

Given the historical lack of consensus over definitions, it has been difficult to determine the incidence of oliguria. Some studies have estimated that up to 18% of medical and surgical intensive care unit (ICU) patients with intact renal function exhibit episodes of oliguria.¹ Furthermore, 88% of ICU patients who develop acute kidney injury (AKI) have a urine output of <0.5 mL/kg/h for 6 hours or more, and 18% have a urine output of <0.3 mL/kg/h for 24 hours or longer.² Overall, AKI in the ICU has a poor prognosis (hospital mortality rates range from 12% for stage 1 to >40% for stage 3), and yet when oliguria is also present along with increased creatinine (at any stage), mortality and the use of renal replacement therapy increase² (Fig. 12-1). Thus, it is essential to understand the physiologic derangements leading to this exceedingly common and serious problem.

PATHOPHYSIOLOGY

Urine output is a function of glomerular filtration, tubular secretion, and tubular reabsorption. Glomerular filtration is directly dependent on intravascular volume and renal perfusion. Renal perfusion in turn is a function of arterial pressure and renal vascular resistance. The intrarenal vasculature is capable of preserving glomerular filtration rate (GFR) in the face of varying systemic pressure through important neurohumoral autoregulating mechanisms that affect the afferent and efferent arterioles. The most important of these neurohumoral mechanisms is the renin-angiotensin-aldosterone system. Oliguria can be due to decreased GFR, increased tubular reabsorption of filtrate, or a combination of both. Oliguria also can be caused by mechanical obstruction to urine flow. It is important to note that AKI need not manifest as oliguria in the intensive care setting, and oliguria is an insensitive clinical manifestation of AKI. Moreover, other factors, such as profound hypokalemia, hypothermia, hyperglycemia, and medications, can all lead to good urine output even in the presence of AKI, confounding the assessment of AKI severity.

Reduction in Glomerular Filtration Rate

Oliguria secondary to a decrease in GFR is usually related to one of the following conditions:

1. Absolute decrease in intravascular volume, which can be due to myriad causes, including trauma, hemorrhage, burns, diarrhea, excessive administration of diuretics, or sequestration of so-called third space fluid, as occurs in acute pancreatitis or abdominal surgery.
2. A relative decrease in blood volume in which the primary disturbance is an alteration in the capacitance of the vasculature due to vasodilation. This abnormality is commonly encountered in sepsis, hepatic failure, nephrotic syndrome, and use of vasodilatory drugs, including anesthetic agents.
3. Decreased renal perfusion in the critical care setting often occurs due to intravascular volume depletion, systemic vasodilation, or impaired cardiac contractility or a combination of the above. Left ventricular dysfunction, either due to underlying coronary artery disease or myocardial depression from sepsis, is the leading cause of impaired cardiac contractility. Decreased renal perfusion due to various other causes, such as thromboembolism, atherosclerosis, aortic dissection, or inflammation (vasculitis, especially scleroderma), affecting either the intra- or extrarenal circulation can also occur but is not common. Although renal arterial stenosis presents as subacute or chronic renal insufficiency, renal atheroembolic disease can present as AKI with acute oliguria. Renal atheroemboli (usually due to cholesterol emboli) usually affect older patients with a diffusive erosive atherosclerotic disease. The condition is most often seen after manipulation of the aorta or other large arteries during arteriography, angioplasty, or surgery.³ It also may occur spontaneously or after treatment with heparin, warfarin, or thrombolytic agents. Drugs such as cyclosporine, tacrolimus, and angiotensin-converting enzyme (ACE) inhibitors, as well as toxins, including radiocontrast dye, cause intrarenal vasoconstriction, resulting in reduced renal plasma flow and consequent oliguria. Decreased renal perfusion can also occur as a result of an outflow problem, such as with abdominal compartment syndrome or (rarely) renal vein thrombosis. Patients who receive massive volume resuscitation (e.g., burns, pancreatitis) and those who undergo major abdominal surgeries are at high risk for intraabdominal compartment syndrome.
4. Acute tubular necrosis (ATN). While this is often an end result of the listed factors, it may also be due to direct nephrotoxicity of agents such as antibiotics, heavy metals, solvents, contrast agents, crystals like uric acid or oxalate, or myoglobinuria.

Mechanical Obstruction

Oliguria secondary to mechanical obstruction can be further classified according to the anatomic site of the obstruction:

1. Tubular-ureteral obstruction may be caused by stones, papillary sloughing, crystals, or pigment.
2. Urethral or bladder neck obstruction, which is usually more common in men and typically due to prostatic hypertrophy or malignancy.

| KDIGO Stage | | UO Only | | | | |
|-------------|---------|---------|---------|---------|---------|--------|
| | | No AKI | Stage 1 | Stage 2 | Stage 3 | Total |
| SC Only | No AKI | 8,179 | 3,158 | 5,421 | 440 | 17,198 |
| | Dead | 4.3% | 5.3% | 7.9% | 17.7% | 5.9% |
| | RRT | 0.0% | 0.0% | 0.1% | 1.1% | 0.1% |
| | Stage 1 | 1,889 | 1,262 | 3,485 | 842 | 7,478 |
| | Dead | 8.0% | 11.3% | 13.0% | 32.1% | 13.6% |
| | RRT | 0.3% | 0.7% | 0.6% | 10.9% | 1.7% |
| | Stage 2 | 618 | 476 | 1,533 | 831 | 3,458 |
| | Dead | 11.3% | 23.9% | 21.5% | 44.2% | 25.5% |
| | RRT | 1.0% | 1.3% | 1.7% | 21.7% | 6.3% |
| | Stage 3 | 371 | 321 | 1,019 | 2,200 | 3,911 |
| | Dead | 11.6% | 38.6% | 28.0% | 51.1% | 40.3% |
| | RRT | 3.2% | 17.8% | 14.2% | 55.3% | 36.6% |
| | Total | 11,057 | 5,217 | 11,458 | 4,313 | 32,045 |
| | Dead | 5.6% | 10.5% | 13.0% | 42.6% | 14.0% |
| | RRT | 0.3% | 1.4% | 1.7% | 34.6% | 5.6% |

FIGURE 12-1 ■ Relationship Between Urine Output (UO) and Serum Creatinine (SC) Criteria and Clinical Outcomes. Top Panel: Results of a large observational study of critically ill patients. Presented are the number of patients, percentage of hospital mortality, and percentage of renal replacement therapy (RRT) for patients by maximum AKI criteria (urine output, serum creatinine, or both). Colors denote similar outcome patterns. Bottom Panel: Corresponding 1-year survival for patients classified as per top panel. (Source: Kellum JA, Sileanu FE, Murugan R, et al. Classifying AKI by urine output versus serum creatinine level. *J Am Soc Nephrol* 2015 January 7, Online. ASN.2014070724 (Permission requested).

3. A malpositioned or obstructed urinary catheter. Oliguria from mechanical obstruction of a urinary catheter should be suspected in any patient who develops oliguria with no predisposing events such as hypotension, shock, or use of nephrotoxins.

■ DIAGNOSTIC APPROACH TO OLIGURIA

Transient oliguria may not be an independent risk factor for morbidity and mortality in critically ill or injured patients, but sustained oliguria (>6 hours) often indicates AKI and has been shown to be independently associated with hospital mortality. Oliguria if not corrected will lead to worsening azotemia, fluid overload, and tissue edema, all of which can cause a variety of adverse outcomes in critically ill patients. Although treating oliguria may confer important physiologic benefits and allow for easier fluid management in intensive care patients, it does not improve important clinical outcomes such as the need for renal replacement therapy, the number of dialysis sessions, survival, or renal recovery. Thus, rapidly determining the cause of oliguria and correcting the underlying cause(s) are crucial to halt the progression of kidney injury.

Rule out Urinary Obstruction

The first step in the approach to a patient with oliguria is to rule out urinary obstruction. A prior history of prostatic hypertrophy may provide some clues to the presence of distal obstruction. However, in the ICU setting, distal obstruction presenting as oliguria is commonly due to obstruction of the urinary catheter (especially in male patients). Hence, in patients with new-onset oliguria, the urinary catheter must be flushed or changed in order to rule out obstruction, especially when no inciting factors are identified. Although uncommon in the acute setting, complete or severe partial bilateral ureteral obstruction may also lead to acute, “acute on chronic,” or chronic renal failure. Early diagnosis of urinary tract obstruction (UTO) is important, since in many cases it can be corrected, and a delay in therapy can lead to irreversible renal injury. Renal ultrasonography is usually the test of choice to exclude UTO,⁴ since this is noninvasive, can be performed by the bedside, and also carries the advantage of avoiding the potential allergic and toxic complications of radiocontrast media. In the majority of affected patients, ultrasonography can establish the diagnosis of hydronephrosis and often establish its cause. Ultrasonography also can be useful to assess the presence of a chronic component to the kidney injury (decreased size of kidney and cortical thinning) and for detecting other causes of renal disease such as polycystic kidney disease. However, under some circumstances, renal ultrasound may not yield good results. For example, in early obstruction or obstruction associated with severe dehydration, hydronephrosis may not be seen on the initial ultrasound examination but may appear later in the course of the disease. Computed tomography (CT) scanning should be performed if the ultrasound results are equivocal or if the kidneys are not well visualized. CT also is indicated if the cause of the obstruction cannot be identified by ultrasonography.

Laboratory Indices

Although most authorities advocate examining the urine sediment, the yield of urine microscopy in the ICU is very low. Urine sediment is typically bland or reveals hyaline and fine granular casts in a prerenal state. By contrast, ATN is often associated with coarse granular casts and tubular epithelial casts. However, the discrimination of these findings is limited, and AKI may be present in the absence of changes in urinary sediment, particularly with sepsis-induced AKI. The main utility of examining the urine sediment is for the detection of red cell casts, which indicate primary glomerular disease. Although rare, these can be present in patients with other systemic illnesses such as systemic lupus erythematosus (SLE). The urine sediment in postrenal failure is often very bland; casts or sediment typically are absent. Occasionally a few red cells and white cells may be seen. Eosinophilia, eosinophiluria, and hypocomplementemia, if present (although insensitive and nonspecific), point to the diagnosis of atheroembolic etiology of acute oliguria.⁵

Table 12-1 lists laboratory values that have been traditionally thought to help in the differentiation of prerenal and intrarenal causes of oliguria. The fractional excretion of filtered sodium (FE_{Na}) is calculated according to the following formula:

$$FE_{Na} = \frac{(\text{urine sodium} \times \text{plasma creatinine})}{(\text{plasma sodium} \times \text{urine creatinine})} \times 100$$

If the calculated FE_{Na} is <1%, a prerenal cause of oliguria is generally suspected. Importantly, interpretation of the FE_{Na} is difficult or impossible if the patient has received diuretic or natriuretic agents (including dopamine and/or mannitol). Interpretation of the FE_{Na} also can be affected by the presence of large amounts of endogenous osmotically active substances in the urine, such as glucose or urea. Drugs that interfere with the renin-angiotensin-aldosterone axis, such as ACE inhibitors or nonsteroidal antiinflammatory agents, also confound the interpretation of FE_{Na}. Several nephrotoxic factors, such as aminoglycosides, cyclosporine, and contrast media, cause afferent arteriolar

TABLE 12-1

Biochemical Indices Useful to Distinguish Prerenal from Intrarenal Acute Renal Failure

| | PRERENAL | RENAL |
|------------------------|----------|-------|
| Osm u (mOsm/kg) | >500 | <400 |
| Na u (mmol/L or mEq/L) | <20 | >40 |
| urea/creatinine | >0.1 | <0.05 |
| u/s creatinine | >40 | <20 |
| u/s osmolality | >1.5 | >1 |
| FE _{Na} (%)* | <1 | >2 |
| FE _{urea} (%) | <25 | >25 |

*[(u Na/s Na)/(u creatinine/s creatinine)] × 100

ARF, acute renal failure; S, serum; U, urine.

vasoconstriction and are hence associated with FE_{Na} values below 1%, mimicking prerenal azotemia. Furthermore, sepsis may result in urine chemistries that resemble prerenal physiology even when renal blood flow is normal or increased.⁶

A low fractional excretion of urea (FE_{urea} < 35%) has been proposed to be more sensitive and specific than FE_{Na} in differentiating between prerenal and renal causes of AKI, especially when diuretics have been administered.⁷ However, numerous studies have demonstrated the limited diagnostic and prognostic utility of urine biochemistry in AKI.⁸⁻⁹

Clinical Parameters

Traditional indicators of fluid status and tissue perfusion—systemic arterial blood pressure, heart rate, body weight, presence of jugular-venous pulsations (JVP), and peripheral edema—can provide important clues about the etiology of oliguria. In the ICU, however, some of these indicators are less useful for a variety of reasons.

The presence or absence of JVP is not an accurate way to assess right ventricular or central venous pressures in the presence of positive pressure ventilation and positive end-expiratory pressure (PEEP). Similarly, peripheral edema is often due to coexistent hypoalbuminemia and decreased oncotic pressure in critically ill patients. Thus, patients can have an excessive volume of total body water and yet be intravascularly volume depleted. BP and heart rate are affected by numerous physiologic and treatment variables and are unreliable measures of volume status.

It is common to assume that one can obtain a more accurate assessment of preload by measuring the central venous pressure (CVP) or pulmonary capillary occlusion pressure (PAOP). However, these parameters do not provide reliable estimates of preload or preload responsiveness.¹⁰ Static measures such as CVP are affected by the presence of atrioventricular valve abnormalities, compliance of the ventricle, and pericardial and abdominal pressures. Even when CVP is low, the value of CVP does not give any information on whether the patient will improve his or her cardiac output to a fluid bolus (i.e., being preload responsive). A cardiac index greater than 3.0 L/min/m² generally suggests adequate preload, but it may not reflect optimal preload.¹¹ The mixed venous oxygen saturation (SvO₂) can serve as a surrogate for cardiac output but again does not define optimal filling. Moreover, SvO₂ can be altered by the ability of tissues to extract and subsequently utilize delivered oxygen. In patients on mechanical ventilation and without spontaneous triggering of the ventilator, an arterial pulse-pressure variation of >13% is strongly predictive of preload responsiveness.¹² However, the use of pulse contour analysis is limited in that it is applicable only in patients who receive >8 mL/kg tidal volume on the ventilator, who do not have arrhythmias, and in whom lung compliance is >30 cm of water. An easier and more applicable test of

preload responsiveness in the ICU setting would be passive leg raising (PLR), which can be done in spontaneously breathing patients and in those with arrhythmias.¹³ A detailed discussion on how to perform this test and its interpretation is beyond the scope of this chapter. In other cases, critical care echocardiography looking at inferior vena cava collapsibility, contractility of the heart, and presence or absence of B lines on lung ultrasound may provide reliable guides to fluid therapy optimization.

Abdominal Compartment Syndrome

Another important and often overlooked reason for acute oliguria is abdominal compartment syndrome (ACS). ACS is defined as symptomatic organ dysfunction that results from an increase in intra-abdominal pressure. Although this condition was initially described in trauma patients, ACS occurs in a wide variety of medical and surgical patients. ACS is sometimes seen after acute severe pancreatitis and major abdominal surgeries requiring large-volume resuscitation, emergent laparotomies with tight abdominal wall closures, or abdominal wall burns with edema. ACS leads to AKI and acute oliguria mainly by directly increasing renal outflow pressure and thus reducing renal perfusion. Other mechanisms include direct parenchymal compression and arterial vasoconstriction mediated by stimulation of the sympathetic nervous and renin-angiotensin systems. Cardiac output also can be compromised by impaired venous return. These factors lead to decreased renal and glomerular perfusion and acute oliguria on this basis. Intraabdominal pressures over 15 mm Hg can lead to oliguria, and pressures over 30 mm Hg can cause anuria.¹⁴

ACS should be suspected in any patient with a tensely distended abdomen, progressive oliguria, and increased airway pressures (transmitted across the diaphragm). The mainstay of diagnosis is the measurement of intraabdominal pressure, and the most common way to assess intraabdominal pressure is to measure the pressure within the urinary bladder. Bladder pressure, obtained by transducing a fluid-filled Foley catheter, has been shown to correlate well with intraabdominal pressure over a wide range of pressures. Decompression of the abdomen with laparotomy, sometimes requiring that the abdomen be left open for a time, is the only definitive treatment for oliguria secondary to ACS.

TREATMENT OF OLIGURIA

Ensuring Adequate Renal Perfusion but Avoiding Fluid Overload

The mainstays of treatment of oliguria are identification and correction of precipitating factors. Hypovolemia should be rectified promptly, but care should be taken to avoid fluid overload. Oliguria should prompt an investigation as to the cause and not just a reflex administration of fluids. In addition, both the volume and type of fluid have been shown to influence the renal function. Too little or too much fluid worsens renal function. Although hypovolemia leading to AKI is intuitive, it is crucial to realize that fluid overload has been consistently shown to impair renal function in several studies.¹⁵⁻¹⁷ Fluid overload impairs renal function by several mechanisms, including increase in the interstitial pressure within the kidney and renal venous pressure, both of which impair the GFR.

Hyperoncotic colloids (20% albumin)¹⁸⁻¹⁹ and hydroxyethyl starch (HES)²⁰⁻²¹ have been shown to worsen renal function, increase the need for renal replacement therapy, and increase patient mortality. These agents should usually be avoided in oliguric patients with or at increased risk of AKI. Although RCTs are lacking, there is considerable observational^{22,23} and experimental²⁴ evidence documenting an association between fluids containing high chloride content (e.g., 0.9% saline) and development or worsening of AKI. Both lactated Ringer's and newer isotonic balanced salt solutions are therefore preferable in patients with or at significant risk of AKI.

Instituting appropriate supportive measures, such as avoidance of nephrotoxic agents and adjustment of doses of renally excreted drugs, is also important. Renal perfusion should be ensured both by correcting hypotension and by supporting appropriate intravascular volume expansion but also by ensuring that intraabdominal and right heart pressures are appropriately managed. The correction of hypotension is especially crucial in sepsis and ischemic AKI, where some of the important autoregulating mechanisms that help preserve GFR in the face of fluctuating BP are disrupted. Vasoactive drugs may be necessary in the ICU setting to maintain adequate renal perfusion pressure and adequate urine output. In general, a target mean arterial pressure (MAP) of 65 mm Hg should be adequate. However, in patients with chronic hypertension and renal vascular disease, the autoregulation curve can be shifted to the right, and higher than normal MAP may be required to ensure adequate renal perfusion.²⁵

Role of Diuretic Agents

The use of diuretic agents in oliguric renal failure is widespread despite the lack of convincing evidence supporting their efficacy. Traditionally, diuretics have been used in the early phases of oliguria to “jump start” the kidney and establish urine flow. Many clinicians believe that the absence of oliguria makes it easier to regulate intravascular volume status. Moreover, nonoliguric renal failure generally has a better prognosis than oliguric renal failure, and clinicians frequently use diuretics in an effort to avoid development of a low urine output state. A large observational study (BEST kidney study) showed that use of diuretics has no beneficial effect on clinical outcomes.²⁶ Furthermore, high doses of loop diuretics can be associated with ototoxicity. Although a cautious trial of diuretics is a reasonable approach in an oliguric patient, and may even be helpful in discerning the cause of oliguria (e.g., furosemide stress test²⁷), this should not be done unless hypovolemia is ruled out and care taken to ensure diuretic usage does not delay initiation of renal replacement therapy when indicated.

Vasoactive Agents

Other agents that have been used to treat oliguria include dopamine and related compounds. Because urine output often increases with the

addition of low-dose dopamine, many intensivists assume that it has a beneficial effect. Indeed, low-dose dopamine had been advocated for nearly 30 years as therapy for oliguric renal failure on the basis of its action on DA1 receptors at doses of <5 µg/kg/min. However, this is now of historical interest only, with there being abundant evidence that low-dose dopamine does not afford any renal protection in oliguria.²⁸

Furthermore, there are important physiologic considerations that argue against a protective role for dopamine or any other dopamine receptor agonists (e.g., fenoldopam, dopexamine) in oliguric states. First, the effect of dopamine agonists on urine output may be merely the natriuretic response mediated by inhibition of sodium/potassium-adenosine triphosphatase (Na⁺/K⁺-ATPase) at the tubular epithelial cell level. In other words, dopamine increases urine output because it is a diuretic. Second, administration of dopaminergic antagonists (e.g., metoclopramide) has not been associated with loss of renal function. Third, the effect of dopamine may be counteracted by increased plasma renin activity in critically ill patients. Fourth, a significant hysteresis effect has been shown for the action of dopamine on renal blood flow. Finally, although dopamine increases renal blood flow, it does not increase medullary oxygenation. Indeed, by increasing solute delivery to the distal tubule, dopamine agonists actually worsen medullary oxygen balance.²⁹ Despite claims to the contrary, newer dopaminergic agonists (e.g., fenoldopam, dopexamine) not only suffer from these limitations but also can induce hypotension, thereby further increasing the risk of renal injury; hence, these should not be used to treat oliguria.³⁰

CONCLUSION

The presence of oliguria should alert the clinician to undertake a diligent search for any correctable underlying causes. The mainstay of treatment is to ensure adequate renal perfusion through optimization of cardiac output and intravascular volume status while avoiding over-resuscitation. The use of diuretics should be limited to treatment of fluid overload, not for treatment of oliguria per se.

Disorders of osmoregulation resulting in dysnatremia—namely, *hypernatremia and hyponatremia*—are exceedingly common clinical problems observed in the critically ill. These abnormalities are usually asymptomatic although at times they can manifest with symptoms ranging from minor to life-threatening. Dysnatremias present at hospitalization or of iatrogenic origin are individual risk factors for increased morbidity and mortality. Dysnatremias present at the time of intensive care unit (ICU) admission were associated with a higher risk of death compared with ICU-acquired dysnatremia. Fluctuations in serum sodium concentrations were independently associated with an increased risk of in-hospital death, even in patients who remained normonatremic during the ICU stay.¹ The key to treatment in an individual patient involves differentiating between acute and chronic disorders and subsequently in balancing the risks of treatment and risks of the disorder.

■ HYPERNATREMIA

Hypernatremia is defined as a serum sodium concentration exceeding 145 mmol/L. It usually affects individuals who have restricted access to water, decreased thirst, or both. In addition, the situation may be exacerbated by pathologic conditions such as acute illnesses that result in increased fluid loss. In the ICU setting, this is a fairly common situation with ongoing fluid loss and inadequate/restricted free water replacement.

In outpatient settings, hypernatremia is mainly found in the geriatric population, whereas in the hospital environment, it is seen in all age groups. The observed incidence is up to 2% of all inpatients, increasing up to 15% among patients admitted to the ICU.^{2,3,4,5} Mortality rates in ICU patients with hypernatremia are reported to be around 32%.⁴ Whereas the increased incidence of hypernatremia in the ICU and increased mortality in these patients is indicative of the underlying disease severity, hypernatremia itself is an independent risk factor of hospital mortality and ICU mortality.^{1,7}

Hypernatremia is usually not a problem of sodium homeostasis but rather a free water deficit resulting from a negative balance between water intake and water excretion. Rarely, hypernatremia can result from increased sodium intake, such as administration of hypertonic saline. Depending on the relative balance of salt and free water intake/loss, hypernatremia can be classified as hypovolemic, euvoletic, or hypervolemic.

Water moves through semipermeable cell membranes to equalize the concentration of solutes in intra- and extracellular fluids. Hypernatremia always causes hypertonicity with extracellular movement of water, leading to cell shrinkage. Sodium can freely cross the systemic capillary membranes, resulting in the same sodium concentration in all extracellular fluids. In contrast, the blood-brain barrier, with its tight endothelial junctions lined by astrocytic foot processes, restricts this sodium movement.⁷ Hypernatremia can therefore cause net loss of brain volume leading to mechanical stress on cerebral vessels leading to intracranial hemorrhage.⁸ Hypernatremia has also been used therapeutically to prevent brain herniation in patients with increased intracranial pressure.⁶

Regulation of water balance is controlled by osmoreceptors present in the hypothalamus. These cells express transient receptor potential time channel subfamily member 1 (TRPV 1) and member 4 (TRPV 4)

channels on the cell membranes^{9,10} and release vasopressin in a linear relationship with increasing plasma sodium concentration above 135 mmol/L.¹¹ Vasopressin binds to V2 receptors on the basolateral membrane of principal cells lining the renal collecting duct⁹ and causes retention of free water, resulting in concentrated urine. Chronic hypernatremia leads to the development of idiogenic osmoles in brain cells. This cellular adaptation prevents cell shrinkage but can lead to idiopathic cerebral edema if the hypernatremia is corrected rapidly with free water replacement.

Symptoms of hypernatremia are mainly neurologic and can range from confusion, weakness, and lethargy in the early stages, progressing to seizures, coma, and even death. Cardiovascular symptoms may relate to volume status, depending upon the cause of hypernatremia. Acute hypernatremia may also cause brain demyelination syndrome.^{12,13}

Prevention of iatrogenic hypernatremia should always be a consideration while treating patients in the ICU. Since the ICU is a monitored environment, predisposed patients should be recognized and identified before the serum sodium rises to an abnormal level. ICU hypernatremia has been proposed as an indicator of quality of care.⁴

Hypernatremia should be aggressively managed in patients having symptoms or when the increase in serum sodium is acute. The basic principle in treatment of hypernatremia is water replacement. Water deficit can be estimated as follows:

$$\text{Water deficit} = (0.6 \times \text{total body weight in kg}) \times (\text{patient's serum sodium concentration} / 140 - 1)$$

where $0.6 \times \text{total body weight in kg}$ is total body water, and 140 is the desired serum sodium concentration. The percentage of water relative to total body weight is actually closer to 50% in women and about 50% in the elderly of both genders.

Since this formula assumes the body to be a closed space, consideration needs to be given for ongoing fluid losses. Another simplified method for calculating free water deficit is 3 mL/kg (elderly woman) to 4 mL/kg (young man) for every 1 mmol/L increase in serum sodium concentration.¹⁴

In chronic hypernatremia, defined as hypernatremia lasting for more than 48 hours or of an unknown duration, the initial therapeutic goal is to decrease the plasma sodium concentration by not more than 10 mmol/L per day.¹⁴ In acute hypernatremia, the rate of decrease in plasma sodium concentration should not exceed 2 mmol/L per hour until the plasma concentration reaches 145 mmol/L. Hyperacute hypernatremia, such as with accidental salt ingestion, manifesting as seizures or intracranial hemorrhage should be aggressively treated with 5% dextrose in water and emergency hemodialysis to restore the normal sodium concentration. Typically, hypernatremia is often undertreated, and there is little risk of inadvertent overcorrection.^{16,17}

■ HYPONATREMIA

Hyponatremia, defined as serum sodium concentration below 136 mmol/L, is the most common electrolyte problem seen in hospitalized patients.¹⁸ The incidence of hyponatremia in hospitalized patients ranges from 30% to 36%.^{19,20} Advanced age is an independent risk factor for the development of hyponatremia due to decreased ability of the body to handle stresses related to salt and water balance.¹⁹

In an aging population, this electrolyte abnormality is increasingly important to understand. Moreover, drugs such as thiazides and non-steroidal antiinflammatory agents commonly used in this age group contribute to decreased renal ability to excrete free water. Critically ill patients also demonstrate impaired renal capacity to excrete free water. In the ICU settings, hyponatremia was noted to be present in 14% of patients at admission²¹ with an overall incidence of 11% to 29%.^{22,23,24} Hyponatremia is also associated with prolonged hospital stay and is an independent predictor of patient mortality. Severe hyponatremia (serum sodium less than 125 mmol/L) has an estimated risk of death of 27% to 40%.^{21,25}

Sodium is the main electrolyte responsible for serum osmolarity. Hyponatremia causes hyposmolarity and intracellular efflux of water. This cellular swelling is most prominent in brain cells, manifesting as varying degrees of cerebral edema with resulting neurologic symptoms. Two mechanisms compensate for cellular swelling. First, increased interstitial hydrostatic pressure due to cerebral edema causes displacement of fluid from the interstitial space into the cerebrospinal fluid (CSF) where some of it may get resorbed. Second, loss of intracellular electrolytes (mainly potassium) and cell-to-cell transfer of osmolytes (taurine, glutamate, etc.) takes place between neurons and the astrocytes that surround them. As a result, the astrocytes swell instead, protecting the neurons from osmotic stress.²⁶ With osmolyte and accompanying water loss, the brain volume returns to normal over time. This adaptive strategy can be harmful at times. In acute hyponatremia, the release of osmolytes such as glutamate may result in seizures; this adaptive mechanism may account for neurologic symptoms such as weakness and lethargy seen in chronic hyponatremia.²⁷ Rapid correction of chronic hyponatremia can cause acute cellular dehydration, with changes similar to those seen in hypernatremia. Once hyponatremia is corrected, the regeneration of osmolytes is slow and can take many days, although intracellular electrolyte accumulation is faster.²⁷

Although mild chronic hyponatremia is often thought to be asymptomatic, it has been associated with an increased incidence of falls, impaired memory, and gait abnormalities.²⁸ Hyponatremia has also been associated with osteoporosis.^{29,30,31} Both these factors add up to an increase in the risk of fractures, especially in the elderly. The major clinical symptoms are neurologic and present more commonly in acute hyponatremia, especially when the serum sodium decreases to less than 120 mmol/L. Initial nonspecific symptoms such as headache, lethargy, and nausea can progress to depressed reflexes, seizures, coma, and death.³² Patients at increased risk of developing encephalopathy are postmenopausal women,³³ children younger than 16 years,³⁴ and those with a preexisting central nervous system (CNS) disorder or space-occupying brain lesion and hypoxemia.³⁵ Increased mortality after developing neurologic symptoms has also been noted in menstruating females.³³ Hyponatremic encephalopathy and increased intracranial pressure can trigger the development of noncardiogenic pulmonary edema.³⁶ This condition is secondary to a CNS-mediated increase in pulmonary vascular permeability and catecholamine release, leading to pulmonary vasoconstriction and hydrostatic edema.³⁵

Treatment of hyponatremia must focus on increasing the sodium concentration and addressing the precipitating cause of the hyponatremia, while preventing any iatrogenic injury related to correction of the sodium level. Restriction of hypotonic fluids, regardless of the cause of hyponatremia, is a basic step/mainstay of such management. Water restriction must be sufficient to achieve negative free water balance (the difference between the total intake and excretion of water) for effective correction of hyponatremia. Urinary sodium and osmolarity should also be measured, especially if the urine is noted to be hypertonic. In patients with syndrome of inappropriate antidiuretic hormone (SIADH) secretion, renal excretion of sodium is increased in response to volume expansion. Therefore administration of normal saline may result in hyponatremia in these patients and should be avoided.

Symptomatic hyponatremia, whether acute (<48 hours) or chronic (>48 hours), needs emergency therapy. Experts agree that the first line of treatment of symptomatic hyponatremia is the administration of 3%

hypertonic saline.³⁷ However, controversy exists regarding the optimal rate of correction of hyponatremia. Each mL of 3% saline will increase the serum sodium concentration by 1 mEq/L. Initial administration of 2 mL/kg of 3% hypertonic saline up to 100 mL should be initially given and repeated every 10-15 minutes if the symptoms persist. Increasing the sodium concentration by 4-6 mEq/L with hypertonic saline is usually sufficient to prevent life-threatening neurologic symptoms of hyponatremia.³⁷

The amount of hypertonic saline necessary to correct the serum sodium concentration to a safe level (e.g., 120 mEq/L) can be estimated by calculating the sodium deficit as follows:

$$\text{Sodium deficit} = 0.5 \times \text{Lean body weight in kg} \times (120 - \text{Observed serum sodium concentration})$$

Cautious correction of hyponatremia and avoidance of iatrogenic neurologic injury is important. The increase in serum sodium concentration should not exceed 10 mEq/L per 24 hours and 18 mEq/L in any 48-hour period.³⁸ Electrolytes should be frequently checked to ensure that the rate of correction is not too high. Resolution of symptoms should be followed by a decrease in the rate of correction.

Unintended overcorrection of hyponatremia is common.³⁹ This result can occur with simultaneous administration of 3% hypertonic saline along with correction of the underlying cause (such as volume administration in dehydration, discontinuation of thiazide diuretics, or correction of the underlying cause of SIADH). Administration of desmopressin every 6-8 hours has been used to therapeutically re-lower the serum sodium concentration in patients who are at risk or who start developing signs and symptoms of osmotic demyelination syndrome (ODS).⁴⁰

In addition to the correction of serum sodium, any coexisting hypokalemia should be simultaneously corrected. Increasing the potassium concentration will indirectly increase serum sodium levels because sodium concentration is a function of exchangeable cations divided by the total body water.⁴¹

Rapid correction (>2 mEq/L per hour) has been linked to ODS in some cases. Other risk factors for ODS are overcorrection and large corrections of hyponatremia (>12 to 25 mEq/L per 24 hours).^{42,43,44,45} Classically, ODS affects the pons (central pontine myelinolysis), but extrapontine lesions are equally common.⁴⁶ In patients who develop this complication, correction of hyponatremia leads to an initial improvement in encephalopathic symptoms followed by a delayed deterioration and development of new permanent neurologic symptoms, including pseudobulbar palsy, quadriparesis, and coma.

Increasing evidence indicates that mild chronic hyponatremia is related to gait and cognition disturbances, thereby increasing the risk of falls and fractures.⁴⁷ Therefore, correction of hyponatremia should be attempted in every ICU patient. Hypertonic saline is rarely recommended in these cases. Besides water restriction, the volume status of the patient should be assessed. In euvolemic patients, SIADH is the most common cause of chronic hyponatremia. ADH restricts free water excretion by the kidneys. Although water restriction is a mainstay of therapy, it may be important to measure the urine osmolarity. In cases of high urine osmolarity, negative free water balance can be promoted by the use of a loop diuretic or demeclocycline (300-600 mg twice a day) that blocks the action of vasopressin on the kidneys. Vasopressin antagonists (vaptans) are a relatively new category of drugs used for the treatment of euvolemic and hypervolemic hyponatremia. Two drugs in this category, tolvaptan and conivaptan, have been approved by the Food and Drug Administration (FDA) in the United States. These drugs are not recommended for the treatment of acute symptomatic hyponatremia, given the failure of some patients to respond.⁴⁸ For chronic hyponatremia patients, these drugs are most effective in hypervolemic hyponatremia of congestive heart failure (CHF) and cirrhosis. Given the lack of mortality benefit and prohibitive cost of treatment, they are not recommended for routine use.⁴⁹

Hypervolemic hyponatremia is associated with the presence of edema and low "effective" volume states, such as CHF. Diminished

effective circulating volume causes release of ADH, causing water retention. Besides correcting the underlying disease process to correct the low “effective” circulating volume, specific treatment includes sodium and water restriction and use of loop diuretics to promote free water loss.

Hypovolemic hyponatremia is usually the result of volume depletion (both salt and water) combined with consumption of hypotonic

fluids. In response to hypovolemia, ADH is released, which further causes free water retention via the kidneys. This positive free water balance results in hypovolemic hyponatremia. Treatment involves intravenous replacement with normal saline to correct the volume depletion that subsequently decreases ADH hormone secretion, thereby allowing kidneys to excrete excess free water, thus correcting the hyponatremia.

KEY POINTS

1. Dysnatremias are risk factors for increased mortality and morbidity.
2. Treatment should be based on differentiating between acute and chronic dysnatremia.
3. Signs and symptoms of dysnatremias are mostly neurologic and primarily are due to the restricted movement of sodium across the blood-brain barrier.
4. Rapid correction of chronic hypernatremia and hyponatremia can predispose a person to cerebral edema and acute demyelination syndrome.
5. Hyponatremia is the most common electrolyte problem seen in hospitalized patients.
6. Vasopressin antagonists (vaptans) are a relatively new category of drugs used for the treatment of euvoletic and hypervolemic hyponatremia.

Potassium is the most abundant intracellular cation and is involved in the regulation of a number of biological functions.¹ Alterations in electrolyte homeostasis frequently occur in critically ill patients, which are likely the result of comorbid disease, prolonged malnutrition, organ dysfunction, and polydrug therapy. Both hyperkalemia and hypokalemia are associated with an increased risk of mortality for intensive care unit (ICU) patients; accordingly, prompt recognition and treatment are essential.²

■ HYPERKALEMIA

Hyperkalemia is defined as a serum potassium concentration of $K^+ > 5.0$ mEq/L.³ As both serum and plasma samples can be used to measure K^+ levels, it is important to know which laboratory specimen is being analyzed. During the clotting process, platelets release K^+ , resulting in higher concentrations in serum as compared to plasma samples.⁴ Elevated K^+ may be due to either true hyperkalemia or pseudohyperkalemia.⁵ *Pseudohyperkalemia* is defined as when serum K^+ exceeds plasma K^+ by >0.4 mEq/L.⁶ Other potential causes of falsely elevated K^+ include cell lysis, thrombocytosis, leukocytosis, delayed processing times, and cold specimen temperatures.^{4,6}

True hyperkalemia occurs as a result of impaired K^+ excretion or transcellular K^+ shifts (Box 14-1). In the absence of renal failure, the kidneys account for approximately 90% of K^+ excretion. Serum K^+ begins to rise only when renal function falls to $<25\%$ of normal.⁵ Factors that have been associated with a greater risk of hyperkalemia include advanced stages of kidney disease, concomitant diabetes mellitus, and the use of agents that impair K^+ elimination, especially drugs that affect the renin-angiotensin-aldosterone system.^{7,8} Aldosterone stimulates the secretion of K^+ into the urine; thus, the deficiency of aldosterone or relative resistance to the effects of aldosterone may result in hyperkalemia.⁹

There are a number of drugs commonly used in the ICU that can cause hyperkalemia by altering K^+ elimination. Potassium-sparing diuretics (e.g., spironolactone, amiloride, and triamterene) inhibit urinary K^+ excretion and increase the risk of hyperkalemia in patients with impaired renal function.¹ Because treatment with spironolactone was found to reduce morbidity and mortality among patients with severe heart failure, the use of this drug has substantially increased in recent years.¹⁰ As a result, hospital admissions for hyperkalemia are more common now than in the past, and deaths in the hospital related to hyperkalemia have increased.¹¹ Angiotensin-converting enzyme inhibitors (ACEIs) reduce aldosterone levels and are associated with a high prevalence of hyperkalemia. Angiotensin receptor blockers (ARBs), when compared to ACEIs, may be associated with a greater risk of hyperkalemia.¹² Due to the inhibition of the cyclooxygenase-2 (COX-2) enzyme, nonsteroidal antiinflammatory drugs (NSAIDs) cause a reduction in renal prostaglandin synthesis. As prostaglandins stimulate the release of renin, NSAIDs may induce relative hyporeninemic hypoaldosteronism, manifesting as hyperkalemia and acidosis.^{13,14} The degree of NSAID-associated hyperkalemia is likely greater in patients with baseline renal insufficiency or those taking other medications that alter K^+ elimination.¹⁵ It has not been firmly established whether the degree of selectivity of COX inhibition impacts the development of hyperkalemia with NSAID administration.^{16,17} Heparin induces reversible hypoaldosteronism and hyperkalemia via a reduc-

tion in the number and affinity of angiotensin II receptors. This effect is independent of the route of heparin administration or the level of anticoagulation achieved.¹⁸ The calcineurin inhibitors, cyclosporine and tacrolimus, impair renal tubular hydrogen ion (H^+) secretion and cause hyperkalemia in the absence of significant renal injury.¹⁹ Other drugs that may alter urinary K^+ excretion and produce hyperkalemia include pentamidine and trimethoprim. The structure of trimethoprim is similar to that of the potassium-sparing diuretic amiloride, and it may reduce urinary K^+ elimination by approximately 40%.²⁰

Changes in transcellular K^+ relationships may lead to severe hyperkalemia in critically ill patients. These may be caused by the release of large amounts of intracellular K^+ or the prevention of extracellular-to-intracellular K^+ shifts. The pH-related effects on transcellular K^+ dynamics are complex as a number of direct and indirect physiologic responses occur simultaneously.¹ Serum hypertonicity causes the movement of water out of the intracellular space, and K^+ follows as a result of solvent drag, increasing K^+ .²¹ As K^+ is primarily an intracellular cation, massive tissue damage from rhabdomyolysis, burns, or trauma can lead to the release of K^+ into the extracellular space, producing hyperkalemia.²² Familial hyperkalemic periodic paralysis is a rare autosomal dominant disorder of ion channel function that presents as episodic weakness and elevations in K^+ .²³

A number of medications affect transmembrane K^+ shifts. β -adrenergic blockers reduce the movement of K^+ into cells and can promote hyperkalemia in patients with renal failure. The development of hyperkalemia with these agents may depend on their relative α - and β -receptor selectivity.²⁴ Succinylcholine is commonly used for paralysis in the ICU and promotes K^+ efflux from myocytes. In the setting of denervation, burns, trauma, or prolonged immobility, the hyperkalemic response can be severe.^{22,25} Digoxin is a cardiac glycoside that inhibits the cell membrane-bound sodium/potassium-adenosine triphosphatase (Na^+ - K^+ -ATPase). Inhibition of this pump leads to a release of K^+ into the extracellular space. Digoxin does not produce hyperkalemia in therapeutic doses but may cause hyperkalemia with toxic levels.²⁶ Insulin promotes the uptake of K^+ into the intracellular space, so insulin resistance or deficiency can result in hyperkalemia.

Clinical Effects

Many of the manifestations of K^+ abnormalities reflect the importance of normokalemia for maintaining membrane potential functionality.² Neuromuscular and cardiac cells are most affected by changes in K^+ homeostasis.²⁷ Hyperkalemia is often asymptomatic but can present as weakness, fatigue, paresthesia, motor paralysis, or quadriplegia.^{2,5} These symptoms are not specific to hyperkalemia and usually occur only in severe cases. The most important consequence of hyperkalemia is a reduction in the myocardial resting membrane potential. Alterations in K^+ result in conduction system abnormalities, with characteristic changes observed on the electrocardiogram (ECG) (Table 14-1). The ECG abnormalities associated with hyperkalemia are often progressive. The first and most common change observed is symmetrical peaking of the T wave. Other abnormalities associated with ongoing hyperkalemia include widening of the QRS complex and reduction in P wave amplitude with its eventual disappearance from the ECG.⁵ Further increases in K^+ can cause the QRS complex to merge with the T wave, resulting in a sine wave pattern. This may eventually

BOX 14-1 Causes of Hyperkalemia**IMPAIRED K⁺ EXCRETION**

Renal failure
 Mineralocorticoid deficiencies
 Renal tubular acidosis (type 4)
 Enzyme deficiencies
 Aldosterone resistance
 Drugs: potassium-sparing diuretics, ACEIs, ARBs, NSAIDs, heparin, trimethoprim, cyclosporine, tacrolimus, pentamidine

SHIFTS OF K⁺ OUT OF CELLS

Hypertonicity
 Tissue breakdown: rhabdomyolysis, burns, trauma
 Drugs: β -adrenergic blockers, digoxin, succinylcholine, arginine, lysine
 Familial hyperkalemic periodic paralysis
 Insulin deficiency or resistance

ACEIs, angiotensin-converting enzyme inhibitors; ARBs, angiotensin receptor blockers; NSAIDs, nonsteroidal antiinflammatory drugs.

TABLE 14-1 Electrocardiogram Changes Caused by Abnormal K⁺

| HYPERKALEMIA | HYPOKALEMIA |
|-------------------------|--------------------------|
| Peaked T waves | Flat T waves |
| Widening QRS complexes | ST segment depression |
| Loss of P waves | U waves |
| Sine wave | QT interval prolongation |
| Ventricular arrhythmias | Ventricular arrhythmias |
| Asystole | |

degenerate into ventricular arrhythmias or asystole. It is important to note that there is significant variability in the K⁺ that results in a particular ECG abnormality, and hyperkalemia does not always present with cardiac manifestations.²⁸

Treatment

The most important goal of treating hyperkalemia is to prevent life-threatening cardiac arrhythmias. Therapeutic strategies are directed at antagonizing the effects of hyperkalemia at the cellular level, shifting K⁺ from the extracellular to the intracellular space, and removing K⁺ from the body. While there is no consensus as to what level of hyperkalemia mandates intervention, patients with serum K⁺ \geq 6.0 mEq/L or those with ECG abnormalities should be emergently treated.^{3,29}

Antagonizing the Effects of Hyperkalemia at the Cellular Level

Calcium chloride and calcium gluconate are salts that antagonize hyperkalemia-induced cardiac membrane excitability. Calcium chloride has greater bioavailability and contains more calcium than calcium gluconate. Despite their beneficial effects on cell membrane excitability, calcium salts do not lower K⁺. Furthermore, the use of calcium in the setting of digoxin toxicity is contraindicated as it may potentiate the drug's negative effects.⁵

Shifting K⁺ From the Extracellular to the Intracellular Space

Insulin increases the cellular uptake of K⁺ by stimulating the Na⁺-K⁺-ATPase pump.³ It is the most effective agent to facilitate transcellular shift, providing the fastest and largest reduction in K⁺.²² The potassium-lowering effect occurs within 15 minutes following administration and

is sustained for 2 to 4 hours. The recommended dose is 10 units of intravenous (IV) regular insulin with 12.5 to 25 g of dextrose to avoid hypoglycemia. This dose will decrease the K⁺ by 0.5 to 1.0 mEq/L.²⁹ β_2 -receptor agonists will also decrease K⁺ by stimulating the Na⁺-K⁺-ATPase pump. Nebulized albuterol is an effective treatment option, lowering K⁺ within 30 minutes.²⁸ Albuterol's reduction in K⁺ is dose dependent. Insulin and β_2 -receptor agonists can each be used as monotherapy, but when these agents are co-administered, a synergistic effect occurs.²⁹ Sodium bicarbonate buffers extracellular H⁺ and promotes the shift of K⁺ into cells. This provides the smallest reduction in K⁺, and its administration should be limited to situations with concurrent metabolic acidosis.^{5,29}

Removal of K⁺ From the Body

A number of diuretics stimulate urinary K⁺ excretion; however, no clinical trials have supported the use of these medications in the treatment of hyperkalemia.²⁸ Cation exchange resins, such as sodium polystyrene sulfonate (Kayexalate), exchange sodium for K⁺ in the colon.³ Each 1 gram of resin removes approximately 1 mEq of K⁺ over 24 hours.⁵ Kayexalate's potassium-lowering effect is slow and may not be appropriate in emergency situations. Furthermore, its use has been associated with intestinal necrosis and bowel perforation.²² Recent studies evaluating newer cation exchange compounds, such as sodium zirconium cyclosilicate (ZS-9) and patiomer, have shown promising results; however, further investigation is needed.^{7,8} Dialysis is the most reliable way of removing K⁺. Both peritoneal dialysis and hemodialysis are options, but hemodialysis is more effective. The speed of K⁺ removal can be adjusted with changes in dialysate K⁺ and the blood flow rate.²⁹ Table 14-2 summarizes these hyperkalemia treatment options.

HYPOKALEMIA

Hypokalemia is defined as serum K⁺ < 3.5 mEq/L.¹ Common causes of hypokalemia include decreased dietary intake, increased excretion, and shifts into the intracellular compartment (Box 14-2). Hypokalemia is often iatrogenic. Diuretic therapy is a well-documented cause of hypokalemia in critically ill patients. Thiazide diuretics indirectly stimulate K⁺ secretion by increasing sodium and fluid delivery to the collecting duct.³⁰ Loop diuretics directly inhibit the Na-K-2Cl transporter in the thick ascending limb of the loop of Henle. Acetazolamide decreases bicarbonate reabsorption in the proximal tubule and increases K⁺ excretion in the distal nephron.³¹ Through their mineralocorticoid effects, fludrocortisone and hydrocortisone can lead to excessive urinary K⁺ wasting. Aminoglycosides, amphotericin B, cisplatin, tenofovir, and foscarnet all promote renal K⁺ loss and can be causes of hypokalemia.³² Penicillin and its synthetic derivatives act as nonreabsorbable anions, enhancing K⁺ secretion.²² A number of drugs promote hypokalemia by altering transcellular K⁺ homeostasis. β_2 -receptor agonists, catecholamines, insulin, and xanthines all stimulate the intracellular uptake of K⁺. Overdoses of thyroxine, risperidone, and quetiapine have all been associated with the development of hypokalemia.^{22,32}

The K⁺ of stool is approximately 55 to 75 mEq/L.³³ As the volume of stool is normally low, fecal K⁺ losses are only 10 mEq/day.³⁴ With increased stool output seen with laxatives, diarrhea, or enemas, K⁺ losses can be significant. The K⁺ in gastric secretions is 5 to 10 mEq/L; thus, vomiting or excessive nasogastric suctioning usually do not directly cause hypokalemia. However, the loss of gastric acid will induce metabolic alkalosis that indirectly stimulates renal K⁺ excretion, possibly exacerbating hypokalemia.³³ The ultimate effect of alkalemia on K⁺ depends on the nature of the underlying disorder, the chronicity, and the degree of renal dysfunction.³¹ Some forms of renal tubular acidosis can promote urinary K⁺ loss. Magnesium deficiency may further exacerbate hypokalemia by increasing distal K⁺ secretion.³⁵ Barium poisoning from radiopaque contrast agents reduces the efflux of K⁺ from muscle cells, causing hypokalemia.³⁶ Delirium tremens is associated with both an increase in renal K⁺ secretion and shifts into the intracellular space.³⁷

TABLE 14-2 Treatment of Hyperkalemia

| TREATMENT | MECHANISM | DOSAGE/COMMENT | ONSET | DURATION |
|--------------------------|------------------------------------|--|--------------|-----------|
| Calcium | Stabilizes myocardial excitability | 10 mL of 10% solution IV (calcium gluconate or calcium chloride) | Minutes | 30-60 min |
| Insulin (regular) | Shifts K ⁺ into cells | 10 U IV + glucose (12.5-25 g) | 15-30 min | 2-4 h |
| Albuterol | Shifts K ⁺ into cells | 10-20 mg inhaled over 10 min | 30 min | 2-3 h |
| Sodium bicarbonate | Shifts K ⁺ into cells | In cases of acidosis | Delayed | — |
| Kayexalate with sorbitol | Removes K ⁺ from body | Oral: 15-30 g Retention enema: 30-50 g | 4-6 h 1 h | — — |
| Loop diuretics | Removes K ⁺ from body | IV, varies by drug and renal function | 15-60 min | — |
| Dialysis | Removes K ⁺ from body | Hemodialysis preferred over peritoneal dialysis in acute cases | 15-30 min | — |

BOX 14-2 Causes of Hypokalemia**DECREASED K⁺ INTAKE****INCREASED K⁺ EXCRETION**

Diarrhea, laxative, enema abuse

Increased renal losses:

Drugs: diuretics, glucocorticoids, aminoglycosides, amphotericin B, cisplatin, tenofovir, foscarnet, penicillin derivatives

Alkalemia

Osmotic diuresis (uncontrolled hyperglycemia)

Renal tubular acidosis

Mineralocorticoid excess:

Primary hyperaldosteronism

Congenital adrenal hyperplasia

Other causes:

Liddle's disease

Enzyme deficiencies

Bartter's syndrome

Magnesium deficiency

SHIFTS OF K⁺ INTO CELLS

Drugs: β -adrenergic agonists, catecholamines, insulin, xanthines, risperidone, quetiapine

Delirium tremens

Hyperthyroidism

Familial hypokalemic periodic paralysis

Barium poisoning

ally, serum K⁺ decreases by approximately 0.3 mEq/L for every 100-mEq reduction in total body K⁺, although this depends on body mass. The presence of ECG abnormalities or respiratory muscle paralysis mandates immediate treatment with IV K⁺. In order to minimize the risk of iatrogenic hyperkalemia, the maximum rate of K⁺ repletion should not exceed 20 mEq/h. In the presence of unstable arrhythmias, more rapid infusions are indicated.³ IV administration of K⁺ should ideally be performed using a central venous catheter as peripheral infusions may cause phlebitis.²² The use of infusion pumps and continuous ECG monitoring is mandatory. IV bolus administration of K⁺ can induce cardiac arrest. In the absence of a medical emergency, oral repletion is the preferred method of administration as it minimizes the risk of rebound hyperkalemia.³⁸ A number of potassium-salt compounds can be used to replenish total body stores. In most cases of hypokalemia, potassium chloride is preferred. Potassium phosphate administration is recommended in patients with concomitant hypophosphatemia, and potassium bicarbonate is preferred in patients with accompanying metabolic acidosis.³⁸ Correction of any coexisting magnesium deficiency is important in treating hypokalemia. Hypomagnesemia promotes renal K⁺ wasting, and the repletion of magnesium will allow for more rapid correction of hypokalemia. Finally the use of protocol-based algorithms for K⁺ replacement may reduce the prevalence of hypokalemia in the ICU.³⁹

KEY POINTS

1. Hyperkalemia and hypokalemia are common electrolyte abnormalities found in ICU patients. Early recognition and intervention are essential to prevent life-threatening complications.
2. ECG changes associated with hyperkalemia include peaked T waves, widening of the QRS complex, loss of P waves, appearance of a sine wave pattern, and ventricular arrhythmias.
3. Calcium salts reduce cardiac membrane excitability and should be given to patients with hyperkalemia and ECG changes.
4. Insulin and β -agonists are effective treatments to shift K⁺ into the intracellular compartment.
5. ECG changes associated with hypokalemia include flattened T waves, ST segment depression, the appearance of U waves, QT interval prolongation, and ventricular arrhythmias.
6. IV K⁺ administration is associated with complications and should be reserved for patients with ECG abnormalities or respiratory muscle paralysis.

Clinical Effects

Hypokalemia is reported to be the most common electrolyte disorder in hospitalized patients, and most cases are asymptomatic.³ Mild effects include fatigue, weakness, nausea, vomiting, and constipation.²² Ongoing reductions in K⁺ result in rhabdomyolysis, ascending paralysis, and respiratory insufficiency.³ The most serious and potentially fatal consequences related to hypokalemia are cardiac. These effects are especially pronounced in patients with hypertension, coronary artery disease, or heart failure.²² Hypokalemia is associated with characteristic ECG changes (Table 14-1). Progressive reductions in K⁺ produce T-wave flattening, ST depression, U waves, QT interval prolongation, ventricular arrhythmias, and cardiac arrest.¹

Treatment

The most important goals in the management of hypokalemia are to recognize and correct life-threatening reductions in serum K⁺. Gener-

Derangements in the metabolism of phosphate commonly affect patients in the intensive care unit (ICU) and can cause significant multiorgan system sequelae, leading to increased morbidity and mortality. For instance, severe hypophosphatemia by itself is a reliable predictor of increased mortality in the septic patient.¹ An approach to recognizing and identifying the causes and clinical implications of this electrolyte disturbance follows; this chapter will provide an overview of phosphate homeostasis, the etiologies, classification, clinical manifestations, and treatment modalities of hypo- and hyperphosphatemic states.

■ PHOSPHATE HOMEOSTASIS

Phosphorus, the essential mineral found in the body, combined with oxygen as phosphate (PO_4) serves a number of crucial physiologic functions. Intracellularly, phosphate mostly exists in organic compounds such as creatine phosphate, 2,3-diphosphoglycerate, and adenosine triphosphate. Phosphorus is a substrate for kinase and phosphatase enzymatic processes critical in intracellular signaling; it is a component of the cell membrane lipid bilayer, a component of hydroxyapatite, the structural matrix of bone, and it serves as a buffer against acid-base derangements.

There is an important distinction between low serum phosphate, referred to as *hypophosphatemia*, and low total body phosphorus stores, referred to as *phosphate depletion*. *Hypophosphatemia* can occur in the setting of normal or even high total body phosphate due to a shift from the extracellular to intracellular compartment. Conversely, phosphate depletion may exist with normal or even elevated levels of serum phosphate in certain conditions such as in diabetic ketoacidosis. There is no common laboratory test to accurately measure total phosphorus stores. In a healthy 70-kg adult, the total body phosphorus content is estimated to be around 700 g (23,000 mmol).²

Laboratory tests instead measure the free inorganic phosphate ions (HPO_4^{2-} , H_2PO_4^- , and PO_4^{3-}), which do not directly reflect total body phosphorus stores because (1) about 80% of total body phosphorus is present in the skeleton as hydroxyapatite; (2) phosphorus is mostly intracellular, with an estimated intracellular to extracellular ratio of 100:1; and (3) transcellular shifts will alter serum phosphate levels without significantly changing total body phosphorus content. Phosphate homeostasis relies on the complex interplay between the gastrointestinal, renal, parathyroid (PTH), and bone axis. PTH increases intestinal phosphate absorption by its effect on vitamin D. Under low serum calcium levels, PTH is secreted and acts on the kidneys to increase 1,25-dihydroxyvitamin D₃ synthesis, which in turn augments both phosphate and calcium transport across the intestinal epithelium. Low serum phosphate levels also stimulate the kidneys to increase hydroxylation of vitamin D to its active form. Under steady-state circumstances, the kidneys regulate phosphate homeostasis by matching urinary excretion with net intake.

Emerging evidence describes a class of regulatory peptides called *phosphatonins*. These peptides decrease serum phosphorus levels by acting on the renal-skeletal-gut axis. Fibroblast growth factor-23 (FGF-23) appears to be the key phosphatonin produced by osteoblasts and osteocytes in response to elevated calcitriol. FGF-23 is secreted into the systemic circulation, decreases renal phosphate resorption, and increases excretion.³

■ HYPOPHOSPHATEMIA

Hypophosphatemia is typically classified as mild (serum phosphate concentration 2.5–3 mg/dL), moderate (1–2.5 mg/dL), or severe (<1 mg/dL). The prevalence of moderate hypophosphatemia ranges between 2.2% and 3.1%, and severe hypophosphatemia between 0.2% and 0.4% in the general hospital population.⁴ Critically ill patients, especially those with diabetic ketoacidosis and sepsis, have a high incidence of hypophosphatemia. Up to 34% of post-elective cardiac surgery patients and nearly all patients after major hepatic procedures develop hypophosphatemia within the first week.^{5,6} Although mild to moderate hypophosphatemia is often subclinical, severe hypophosphatemia can be associated with significant morbidity. All-cause mortality in patients with serum phosphate concentrations less than 1 mg/dL is as high as 30%.⁷

Common causes of hypophosphatemia are summarized in Box 15-1. Respiratory alkalosis can induce intracellular shifts of phosphate. Certain therapies instituted in the ICU, including overly aggressive diuresis, renal replacement therapy,⁸ and erythropoietin therapy,⁹ increase the risk of hypophosphatemia. Hyperparathyroidism and proximal renal tubular disorders impair phosphate resorption. Total body phosphate depletion also follows extreme catabolic states such as burns or sepsis.

Total body phosphate stores become depleted during a state of severe starvation, despite lab values that may show normal serum phosphate levels. Initially, the body adapts to a fasting state by glycogenolysis of the liver stores, which deplete after 24 hours. The body then decreases insulin secretion, shifting from glycogen to protein and fat catabolism as a source of glucose. Reintroduction of nutrition, especially a high carbohydrate load, increases insulin levels; anabolic pathways are activated, and lipolysis reverts to lipogenesis. The subsequent *refeeding syndrome* precipitates from low phosphate supply to high anabolic demand, as well as an intracellular compartment shift caused by insulin. Therefore, identifying high-risk patients, anticipating these changes before initiating feeding, slowly increasing nutritional intake, and close monitoring of electrolytes with appropriate repletion is imperative.^{10,11}

The patient in diabetic ketoacidosis is also at serious risk for phosphate depletion. Although plasma levels may be normal, total body stores are often depleted first due to the acidemia, which promotes transcellular phosphate shift and then through high renal losses through osmotic diuresis. Once insulin therapy is initiated, the acidemia is corrected, which pushes phosphate from the serum back into the cell, further exacerbating the problem.¹²

Development of the cardiac, respiratory, or neurologic manifestations of hypophosphatemia depends on the severity (typically serum levels below 1.0 mg/dL) and chronicity (Box 15-2). Proximal and/or diffuse skeletal muscle weakness with or without bone pain or rhabdomyolysis can be profound.¹³ ATP depletion in myocardial cells results in a well-described reduction in cardiac contractility that corrects with phosphate repletion. Hypophosphatemia can also cause a reversible depression in diaphragmatic contractility associated with respiratory failure and ventilator dependence.¹⁴ Neurologically, a wide spectrum of disorders such as peripheral or central neuropathy, tremors, paresthesias, encephalopathy, and seizures has been reported.

BOX 15-1**Common Causes of Hypophosphatemia**

Trans-cellular shift
 Refeeding syndrome
 Respiratory alkalosis
 Insulin administration
 Renal losses
 Diuretic therapy
 Volume expansion
 Osmotic diuresis
 Hyperparathyroidism (primary or secondary)
 Proximal renal tubular dysfunction
 Fanconi syndrome
 Insufficient intestinal absorption
 Malnutrition
 Phosphate-binding antacids
 Vitamin D deficiency
 Chronic diarrhea
 Steatorrhea
 Nasogastric suctioning
 Vomiting
 Malabsorption syndromes
 Extreme catabolic states
 Burns
 Trauma
 Sepsis

BOX 15-2**Clinical Manifestations of Severe Hypophosphatemia**

Respiratory
 Acute respiratory failure
 Ventilator dependence
 Musculoskeletal
 Muscle weakness
 Rhabdomyolysis
 Bone demineralization
 Hematologic
 Hemolysis
 Disorders of leukocyte phagocytosis or chemotaxis
 Neurologic
 Altered mental status
 Gait disturbance
 Paresthesias
 Cardiovascular
 Cardiomyopathy
 Decreased inotropy
 Cardiac dysrhythmias

Because phosphate serves as a buffer against acid-base derangements, hypophosphatemia influences the interpretation of acid-base status. The anion gap used to estimate unmeasured anions is typically lower for a patient with low measurable anions (i.e., either hypophosphatemia or hypoalbuminemia, or both). Therefore, the presence of a “normal” value for the calculated anion gap, under 10 or 12, in the setting of profound hypophosphatemia can actually suggest the presence of unmeasured anions. As a rule, the expected anion gap (in mEq/L) equals twice the serum albumin concentration (in g/dL) plus half the serum phosphate concentration (in mM/L).

Severe hypophosphatemia (phosphate concentration <1 mg/dL) mandates intravenous replacement, which has been found to vary widely from clinician to clinician in regard to dosages and speeds of infusion.¹⁵ One common regimen recommends continuous infusion of potassium phosphate 9 mmol (279 mg) given over 12 hours. Depending on the severity of phosphate deficit a weight-based regime ranging from 0.08 mmol/kg (2.5 mg/kg) or 0.16 mmol/kg (5 mg/kg) over 6 hours can be infused.¹⁶ Phosphate should *not* be administered by the

BOX 15-3**Common Causes of Hyperphosphatemia**

Renal
 Acute or chronic renal failure
 FGF-23 Deficiency
 Increased renal resorption:
 Hypoparathyroidism
 Thyrotoxicosis
 Cellular injury
 Rhabdomyolysis
 Tumor lysis syndrome
 Hemolysis
 Medication related
 Abuse of phosphate-containing laxatives
 Excessive (iatrogenic) phosphate administration
 Bisphosphonate therapy

IV route to patients with renal failure, and in every patient, close attention must be paid to the side effects of IV phosphate repletion; namely, metastatic calcification, hypocalcemia, hyperkalemia associated with potassium-containing supplements, volume excess, hyponatremia, metabolic acidosis, and hyperphosphatemia.

HYPERPHOSPHATEMIA

Hyperphosphatemia is defined as a serum phosphate level above 4.5 mg/dL; symptoms may be clinically significant at levels over 5 mg/dL. Causes of hyperphosphatemia are summarized in **Box 15-3**. Because of the kidney's high capacity to excrete phosphorus, hyperphosphatemia rarely occurs in the absence of kidney disease or from high intake alone. Instead, the most common cause of hyperphosphatemia in the critically ill patient is renal failure. Renal insufficiency impairs phosphate excretion and results in a positive phosphate balance, especially in stage IV and V of chronic kidney disease. Kidney injury also affects the normal adaptive bone mineralization process through hormonal and metabolic mechanisms (i.e., renal osteodystrophy).¹⁷ Bone normally acts as the body's primary phosphate reservoir; renal disease causes an increase in net bone resorption, releasing phosphate from the skeleton into the serum.

Iatrogenic hyperphosphatemia has been reported in the literature, most commonly with the use of phosphate-containing laxatives, bisphosphonate therapy, liposomal amphotericin B, or overly generous phosphate replacement. The use of phosphate-containing colorectal laxatives has been reported to cause clinically significant hyperphosphatemia and even cardiac arrest.¹⁸ Bisphosphonate therapy has been reported to cause hyperphosphatemia in the setting of renal insufficiency.¹⁹ Treatment of invasive fungal infections with liposomal amphotericin B has also been associated with hyperphosphatemia, which resolves after transition to amphotericin B lipid complex.²⁰

Hyperphosphatemia and hypocalcemia are often found together as a result of changes in the renal-parathyroid-bone axis. Loss of calcitriol production capacity in kidney disease leads to decreased intestinal calcium absorption and stimulation of parathyroid hormone production (i.e., secondary hyperparathyroidism). At the same time, however, normal bone resorption is impaired by high levels of phosphate.²¹

The two main approaches to managing hyperphosphatemia include limiting intake and enhancing urinary excretion (**Box 15-4**). In the absence of end-stage renal disease, phosphate excretion can be optimized with saline infusion (volume diuresis) and diuretic administration. Any patient with life-threatening hyperphosphatemia should be considered for dialysis. Oral phosphate binders decrease the absorption of phosphate in the gut and are a mainstay for preventing and treating hyperphosphatemia in patients with chronic renal failure. Calcium and aluminum salts are widely used. Calcium salts such as calcium acetate can produce hypercalcemia and metastatic calcification from a high

BOX 15-4 Treatment of Hyperphosphatemia

Decreased absorption/intake:

- Avoid oral intake of phosphate
- Avoid iatrogenic causes (i.e., phosphate-containing enemas, liposomal amphotericin B)
- Oral phosphate binders (i.e., calcium acetate, sevelamer)
- Slow and cautious repletion of phosphate

Increased excretion:

- Intravenous fluids (volume diuresis)
- Diuretic therapy
- Hemodialysis

calcium-phosphorus ($\text{Ca} \times \text{PO}_4$) product, however, in the patient with concomitant hypocalcemia they become the best choice. For patients requiring renal replacement therapy, chronic management of hyperphosphatemia with calcium-free phosphate binders (e.g., sevelamer hydrochloride [Renagel]) may reduce long-term mortality by preventing cardiovascular complications associated with a high $\text{Ca} \times \text{PO}_4$ product.²² However, these investigations have been observational in nature, and to date, data are lacking to convincingly show that normalization of phosphate in chronic hyperphosphatemia decreases morbidity of chronic kidney disease.

KEY POINTS

1. Phosphate has crucial physiologic functions in cell metabolism, oxygen delivery, enzymatic processes, energy metabolism, and bone integrity.
2. Derangements in phosphate balance have serious clinical sequelae in the critically ill. Severe hypophosphatemia is independently associated with increased mortality in the septic patient.
3. Phosphate regulation relies on the renal-gastrointestinal, parathyroid, and bone axis.
4. Hypophosphatemia is caused by reduced intake/intestinal malabsorption, transcellular shifts, and/or excessive renal excretion. Phosphate repletion regimens are varied in dosing and duration.
5. The kidney has a high capacity to eliminate phosphate. Hyperphosphatemia is rare in the absence of renal insufficiency.

ANNOTATED REFERENCES

Byrnes MC, Stangenes J. Refeeding in the ICU: an adult and pediatric problem. *Curr Opin Clin Nutr Metab Care* 2011;14(2):186–192.

This comprehensive review of refeeding syndrome takes an organ-system approach to the constellation of signs and symptoms that develop from the abrupt provision of nutrition after a period of malnutrition. The diagnostic and treatment modalities, including laboratory studies and electrolyte repletion as well as clinical pathways for correcting undernutrition, are explained.

Cavalli L, Mazzotta C, Brandi ML. Phosphatonins: physiological role and pathological changes. *Clin Cases Miner Bone Metab* 2012;9(1):9–12.

This article describes role of phosphatonins on phosphate homeostasis via their action on the bone-parathyroid-kidney axis, specifically via the peptide FGF23 and its cofactor Klotho. The clinically relevant pathologies related to altered expression of FGF23, either from mutations of the FGF23 gene or other genes that regulate its signaling pathway, are also described.

Gaasbeek A, Meinders AE. Hypophosphatemia: an update on its etiology and treatment. *Am J Med* 2005;118(10):1094–1101.

This article describes the spectrum of physiologic processes affected by phosphate homeostasis. It reviews phosphate imbalance, its relevance in patient care, as well as its appropriate management.

The RENAL Replacement Therapy Study Investigators. Intensity of continuous renal-replacement therapy in critically ill patients. *N Engl J Med* 2009;361(17):1627–1638.

A multicenter, randomized trial to assess whether higher intensity of continuous renal replacement therapy decreases all-cause mortality at 90 days. The study found no difference in the primary outcome of mortality, but did note a significantly increased incidence of hypophosphatemia (65.1% versus 54%; $P < 0.0001$) in intensive renal replacement therapy.

Magnesium is an important ion that participates as a cofactor in over 300 enzymatic reactions, especially in those involving adenosine triphosphate (ATP). Hypomagnesemia is common in critically ill patients and is associated with increased mortality.¹

CELLULAR PHYSIOLOGY AND METABOLISM OF MAGNESIUM

Magnesium is a divalent cation (Mg^{++}) that is predominantly localized to the intracellular compartment (99%). It is the second most abundant intracellular cation after potassium and plays an important role in cellular metabolism and homeostasis. At the cellular level, Mg^{++} influences membrane function by regulating ion transport; Mg^{++} is required for sodium/potassium-adenosine triphosphatase (Na^+/K^+ -ATPase) activity, which maintains transmembrane gradients for Na^+ and K^+ .^{2,3} Mg^{++} also regulates intracellular calcium (Ca^{++}) flux by competing for Ca^{++} binding sites and influencing intracellular Ca^{++} transport.^{2,3} It is also an essential cofactor for most ATP-requiring processes. Intracellular Mg^{++} is required for numerous critical biochemical processes, including DNA synthesis, activation of gene transcription, initiation of protein synthesis, and regulation of energy metabolism.^{2,3}

Total body magnesium (21 to 28 g) is distributed in bone (53%), muscle (27%), soft tissue (19%), and blood (0.8%).² The normal concentration of total magnesium in serum is 1.5 to 2.3 mg/dL. Approximately 19% of circulating magnesium is bound to proteins, whereas 14% is complexed to plasma anions (citrate, phosphate, and bicarbonate). The majority of magnesium in plasma exists in its ionized form (67%), which represents the physiologically active species.² Consequently, the measurements of total serum magnesium may not accurately reflect the relative abundance of circulating Mg^{++} .^{1,2}

Magnesium homeostasis is maintained by the small intestine, kidney, and bone.^{2,4} Unlike calcium, there are no hormonal mechanisms for regulating Mg^{++} . Consequently, normal renal filtration and the reabsorption of Mg^{++} represent important regulatory mechanisms for Mg^{++} homeostasis.^{2,4} Non-protein-bound Mg^{++} is filtered by the glomerulus. Under normal conditions, up to 95% of filtered Mg^{++} is reabsorbed either in the proximal tubule (35%) or in the thick ascending loop of Henle (60%). Mg^{++} reabsorption in the loop of Henle is linked to sodium chloride ($NaCl$) transport and is inversely related to flow. Consequently, diuretic use and other conditions associated with increased tubular flow result in decreased Mg^{++} reabsorption.^{2,4} Under conditions of persistent Mg^{++} deficiency, the mobilization of Mg^{++} from bone also represents a potential homeostatic mechanism.²

PREVALENCE AND ETIOLOGY OF HYPOMAGNESEMIC IN PATIENTS IN THE INTENSIVE CARE UNIT

The reported prevalence of hypomagnesemia in adult intensive care unit (ICU) admissions ranges from 15% to 60% of cases.^{1,2} Most commonly, severe ionized hypomagnesemia in ICU settings is encountered following liver transplantation and in patients with severe sepsis,¹ but many conditions encountered in ICU patients can be associated with hypomagnesemia (Table 16-1). Hypomagnesemia is associated with an increased risk of mortality.¹

CLINICAL SIGNS AND SYMPTOMS OF HYPOMAGNESEMIC

Hypomagnesemia is frequently asymptomatic in critically ill patients and is commonly identified through routine laboratory studies.^{4,5} However, the relationship between hypomagnesemia and intracellular magnesium depletion is complex. Hypomagnesemia is most commonly seen in conjunction with hypokalemia, hypocalcemia, and/or other electrolyte abnormalities. Consequently, determining the clinical consequences of isolated hypomagnesemia has been difficult. In most instances, symptoms were attributed to Mg^{++} deficiency only after other electrolyte abnormalities had been corrected.^{2,4,5} As summarized in Table 16-2, the clinical sequelae of Mg^{++} deficiency are most commonly related to the cardiovascular, metabolic, and neuromuscular systems.

Hypomagnesemia is associated with electrocardiogram (ECG) changes similar to those observed in patients with hypokalemia: flattened T-waves, U-waves, and a prolonged QT interval. Magnesium is a cofactor for Na^+/K^+ -ATPase in cardiac tissue.^{2,4-6} Hypomagnesemia is associated with a variety of dysrhythmias, including atrial fibrillation, multifocal atrial tachycardia, ventricular tachycardia, and torsades de pointes.⁴⁻⁶ The administration of intravenous magnesium sulfate ($MgSO_4$) should be the initial therapy for torsades de pointes and should be used as an adjunctive treatment for refractory ventricular dysrhythmias.^{2,4-6} Magnesium administration during acute myocardial infarction is not recommended in the latest guidelines.⁷⁻⁹

Hypomagnesemia is commonly associated with both hypokalemia and hypocalcemia.⁴ The medications and homeostatic changes that affect magnesium handling often affect K^+ handling as well. In addition, hypomagnesemia promotes the renal losses of K^+ . Thus, hypokalemia can be refractory to potassium supplementation unless magnesium is replaced first.^{2,4} A somewhat similar condition is noted for hypocalcemia because hypomagnesemia suppresses parathyroid hormone release and activity.¹⁰ Consequently, hypocalcemia can be refractory to Ca^{++} replacement unless Mg^{++} is replaced as well.^{2,4} Hypomagnesemia has been shown to be associated with an increased incidence and degree of lactic acidosis.¹¹

Magnesium produces a depressant effect on the nervous system through its ability to cause presynaptic inhibition.^{2,4,6} It may also depress the seizure threshold by its ability to competitively inhibit N-methyl-D-aspartate receptors.^{2,4-6} The neurologic and neuromuscular manifestations of hypomagnesemia include coma, seizures, weakness, and signs of muscular irritability. The supplementation of magnesium might provide neuroprotective properties in patients with traumatic brain injury and prevent cerebral vasospasm in patients with aneurysmal subarachnoid hemorrhage.^{12,13} In addition, the administration of Mg^{++} therapy is commonly used in pregnant patients with preeclampsia or eclampsia.^{4,5}

Magnesium replacement has been used to treat bronchospasm in patients with asthma.^{4,5} The proposed mechanism of action for the therapeutic benefit of Mg^{++} in bronchospasm involves its relaxant effects on smooth muscle. Some studies have demonstrated improved forced expiratory volume in the first second of expiration (FEV₁) following intravenous magnesium administration or improved peak flow rates with nebulized magnesium, but these findings have not been confirmed.⁵

TABLE 16-1 Etiology of Hypomagnesemia in the ICU^{1,2,4-6}

| | |
|--------------------------------|---|
| Decreased GI intake | Magnesium-poor diet or total parenteral nutrition; malabsorption syndrome; short bowel syndrome |
| Increased GI losses | Chronic diarrhea; intestinal and biliary fistulae; nasogastric suctioning; vomiting |
| Intrinsic renal losses | Interstitial nephropathy; postrenal transplantation; postobstructive or postacute kidney injury diuresis |
| Drug-induced renal losses | Loop and thiazide diuretics; aminoglycosides; amphotericin B; cyclosporine; cisplatin; granulocyte colony-stimulating factor |
| Endocrine and metabolic causes | Hyperaldosteronemia; hyperparathyroidism; hyperthyroidism; SIADH; diabetic and alcoholic ketoacidosis; hypophosphatemia; hypercalcemia; hypoalbuminemia |
| Magnesium redistribution | Acute pancreatitis; administration of epinephrine, insulin; refeeding syndrome; massive blood transfusion |
| Other causes | CRRT; CPB; severe burns |

GI, gastrointestinal; SIADH, syndrome of inappropriate antidiuretic hormone; CRRT, continuous renal replacement therapy; CPB, cardiopulmonary bypass.

TREATMENT OF HYPOMAGNESEMIA

The management of hypomagnesemia should include the identification and correction of underlying causes and the replacement of magnesium. The degree of hypomagnesemia, severity of clinical symptoms, associated electrolyte abnormalities, and renal function should be assessed prior to initiating Mg^{++} therapy.

In general, intravenous administration of Mg^{++} is preferred in symptomatic critically ill patients. However, caution must be used with Mg^{++} replacement when renal dysfunction is present, since severe hypermagnesemia may result. Current recommendations for Mg^{++} replacement therapies are of somewhat limited value owing to the lack of adequately controlled studies. Magnesium may be administered intravenously as $MgSO_4$ (1 g = 4 mmol) or $MgCl_2$ (1 g = 4.5 mmol) and orally as magnesium gluconate (500 mg = 1.2 mmol) or magnesium oxide (400 mg = 6 mmol). When intravenous Mg^{++} replacement is used, a bolus followed by continuous infusion or infusion alone is preferred, since renal filtration and excretion may limit Mg^{++} retention. For the management of torsades de pointes, 1 to 2 g of intravenous

$MgSO_4$ over 5 minutes is recommended. For the urgent treatment of hypomagnesemia, an intravenous bolus of 8 to 12 mmol of Mg^{++} (2-3 g $MgSO_4$), followed by an infusion of 40 mmol Mg^{++} (10 g $MgSO_4$) over the next 5 hours should be considered.

KEY POINTS

1. Hypomagnesemia is one of the most common electrolyte disturbances encountered in ICU patients.
2. Hypomagnesemia is frequently asymptomatic; however, in ICU patients it is associated with increased mortality.
3. Hypomagnesemia in ICU patients manifests as disturbances in the cardiovascular, neuromuscular, and metabolic systems.
4. Aggressive intravenous administration of magnesium is indicated in cardiac arrhythmias, including torsades de pointes, preeclampsia/eclampsia, and status asthmaticus.

Abnormal serum calcium concentration is a common finding in critically ill patients. The prevalence of hypocalcemia in intensive care unit (ICU) patients ranges from 70% to 90% when total serum calcium is measured and from 15% to 50% when ionized calcium is measured.¹ Hypercalcemia less frequently occurs, with a reported incidence of <15% in critically ill patients.² Hypocalcemia is associated with injury severity and mortality in critically ill patients.^{1,3-5} However, whether low serum calcium is protective, harmful, or simply prognostic in critical illness is unclear. Therefore, in most instances, the management of hypocalcemia involves treating the underlying medical condition(s), except when patients are symptomatic or hemodynamically unstable.

CALCIUM PHYSIOLOGY AND METABOLISM

Calcium is a divalent ion (Ca^{2+}) involved in critical biologic processes like muscle contraction, blood coagulation, neuronal conduction, hormone secretion, and the activity of various enzymes.³⁻⁵ Therefore, it is not surprising that intracellular and extracellular calcium levels, like pH, are tightly regulated. A normal adult contains approximately 1 to 2 kg of total body calcium, which is primarily located in bone (99%) as hydroxyapatite.^{1,3,5} Skeletal stores of calcium represent an unlimited reservoir that is predominantly regulated by extracellular Ca^{2+} , parathyroid hormone (PTH), and calcitonin. Extracellular concentrations of Ca^{2+} are typically 1 to 10,000 times greater than cytoplasmic Ca^{2+} levels.^{1,3} Similarly, the majority of intracellular calcium (>90%) is found in subcellular organelles (e.g., mitochondria, microsomes, and endoplasmic or sarcoplasmic reticulum) as opposed to in the cytoplasmic compartment. Ca^{2+} -mediated cell signaling involves rapid changes in cytoplasmic Ca^{2+} from both internal and external stores.^{6,7} Cytoplasmic Ca^{2+} influx occurs through cell membranes by receptor-activated, G-protein-linked channels and the release of internal Ca^{2+} from endoplasmic or sarcoplasmic reticulum (ER/SR) by second messengers.⁶ The efflux of cytoplasmic Ca^{2+} involves the transport of Ca^{2+} across the cell membrane and into the ER/SR via specific transporters.⁶⁻⁸ These tightly controlled pulsations of cytoplasmic Ca^{2+} thus regulate signal strength and frequency for calcium-mediated cellular functions. Alterations in Ca^{2+} signaling have been identified in myocytes, hepatocytes, neutrophils, and T lymphocytes during sepsis and may contribute to the development of organ dysfunction during catabolic illness (for review see Ref. 7).

Extracellular calcium homeostasis is maintained by the coordinated actions of the gastrointestinal tract, kidneys, and bone.^{1,3} Levels of extracellular Ca^{2+} are detected by calcium-sensing receptors on parathyroid cells.⁸ In response to low serum Ca^{2+} , the parathyroid glands secrete PTH, which reduces the renal reabsorption of phosphate, increases renal calcium reabsorption, and stimulates renal hydroxylation of vitamin D.^{1,3} PTH and 1,25-dihydroxy vitamin D (calcitriol) promote the release of calcium from bone by activating osteoclasts.^{1,3} Calcitriol also stimulates intestinal absorption of dietary calcium and regulates PTH secretion by inhibiting PTH gene transcription. PTH secretion is also influenced by serum phosphate concentration. High circulating phosphate levels stimulate PTH secretion by lowering extracellular Ca^{2+} . Magnesium is required for the release of PTH from parathyroid cells and may explain the occurrence of hypocalcemia in

patients with magnesium deficiency. Calcitonin is a calcium-regulating hormone secreted by the parafollicular C-cells of the parathyroid gland during hypercalcemia. Although calcitonin inhibits bone resorption and stimulates the urinary excretion of calcium, this hormone does not appear to play a major role in calcium homeostasis in humans.^{1,3}

The normal concentration of ionized calcium in the extracellular space (plasma and interstitium) is 1.2 mmol/L and represents 50% of the total extracellular calcium. The remaining 40% is bound to plasma proteins, and 10% is combined with citrate, phosphate, or other anions. Total serum calcium normally ranges from 9.4 to 10.0 mg/dL (2.4 mmol/L). The distribution of ionized and bound calcium may be altered in critically ill patients. Chelating substances like citrate and phosphate may influence the abundance of ionized Ca^{2+} . Increased free fatty acid levels caused by lipolysis or parenteral nutrition result in increased binding of calcium to albumin.⁹ Protein-bound calcium is also increased during alkalosis and reduced during acidosis.^{1,3} Correcting total serum calcium for albumin and pH does not accurately estimate ionized Ca^{2+} .^{10,11} Therefore, a direct measurement of ionized serum calcium has been found to be the most accurate way to determine the concentration of this cation, and hence this approach is indicated in critically ill patients.¹²

HYPOCALCEMIA IN CRITICALLY ILL PATIENTS

Ionized hypocalcemia is frequently seen in critically ill patients with sepsis, pancreatitis, severe traumatic injuries, or following major surgery. The incidence of hypocalcemia ranges from 15% to 50%.³ The degree of hypocalcemia correlates with illness severity as measured by the Acute Physiology and Chronic Health Evaluation (APACHE) II score and is associated with increased mortality in critically ill patients.⁴ In particular, the degree of systemic inflammation, as measured by cytokine, tumor necrosis factor (TNF)-alpha, and pro-calcitonin levels, appears to correlate with hypocalcemia in ICU patients.¹¹ Potential etiologies for the hypocalcemia of critical illness include impaired PTH secretion or action, vitamin D deficiency or resistance, calcium sequestration or chelation, or impaired mobilization of Ca^{2+} from bone (Table 17-1).

Hypocalcemia in the ICU is rarely caused by primary hypoparathyroidism. However, sepsis and systemic inflammatory response syndrome (SIRS) are commonly associated with hypocalcemia, which is caused in part by the impaired secretion and action of PTH and the failure to synthesize calcitriol.^{1,3,11} Hypomagnesemia may contribute to hypocalcemia during critical illness via inhibitory effects on PTH secretion and target organ responsiveness.^{1,3,5} However, the presence of hypomagnesemia only weakly correlates with hypocalcemia in ICU patients.⁴

In many instances, the hypocalcemia of critical illness is multifactorial in etiology. Elderly patients are at an increased risk for vitamin D deficiency due to malnutrition, poor intestinal absorption, and hepatic or renal dysfunction.³ In obese patients with previous gastric bypass, the intestinal absorption of calcium dramatically decreases despite reasonable vitamin D levels and recommended calcium intake.¹³ Renal failure may precipitate hypocalcemia via the decreased formation of calcitriol and hyperphosphatemia and the chelation of ionized calcium.^{1,3} The use of continuous renal replacement therapy in critically ill patients is associated with significant magnesium and calcium

losses. This results in electrolyte replacement requirements that often exceed the calcium and magnesium supplementation provided in standard parenteral nutrition formulas.¹⁴ Other potential causes of ionized hypocalcemia in critically ill patients include alkalosis (increased binding of Ca^{2+} to albumin), medications (anticonvulsants, antibiotics, diphosphonates, and radiocontrast agents), massive blood transfusion, sepsis, and pancreatitis.^{1,3-5} More recently, the infusion of high doses of propofol have been shown to reduce circulating calcium concentrations by elevating serum PTH levels, but the physiologic significance of this phenomenon is unclear.¹⁵ Ionized hypocalcemia (<1.0 mmol/L) is associated with prehospital hypotension and represents a better predictor of mortality in severely injured patients than base deficit.¹⁶ The exact reasons for this observation are unclear but potentially relate to head injury and/or the presence of hemorrhagic shock. Injured patients receiving blood transfusions may develop hypocalcemia as a consequence of Ca^{2+} chelation by citrate, which is used as an anticoagulant in banked blood.¹⁷⁻¹⁹ The incidence of transfusion-related hypocalcemia is related to both the rate and volume of blood transfusion.^{17,18} When blood transfusions are administered at a rate of 30 mL/kg/h (e.g., 2 L/h in a 70-kg patient) and hemodynamic stability is maintained, ionized Ca^{2+} levels are preserved by physiologic compensatory mechanisms.¹⁹ Transient hypocalcemia may be observed with rapid transfusion and can be prolonged or exacerbated by hypothermia, renal failure, or hepatic failure.¹⁷⁻¹⁹ Consequently, ionized calcium should be monitored and replaced when clinically indicated during massive transfusion. However, hypocalcemia tends to normalize within four days after ICU admission, and failure to normalize in severely hypocalcemic patients may be associated with increased mortality. Calcium replacement does not typically improve normalization or reduce mortality.²⁰

HYPOCALCEMIA IN SEPSIS AND PANCREATITIS

Hypocalcemia is especially common in critically ill patients with systemic infection or pancreatitis.^{1,3,4,7,11} In animal models, serum calcium concentrations decrease following endotoxin infusion.^{7,11,21,22} When septic patients with hypocalcemia were compared with nonseptic controls, increased TNF- α and interleukin-6 levels correlated with ionized hypocalcemia.²³ Septic patients with hypocalcemia may

demonstrate increased or decreased PTH levels; however, urinary excretion of calcium and bone resorption appear to be preserved when compared to controls.^{11,21} Procalcitonin levels are increased during sepsis-induced hypocalcemia, but mature calcitonin only exerts a weak and transient effect on circulating calcium level.^{23,24} Collectively, the results suggest that hypocalcemia during severe infection has a multifactorial etiology but that inflammatory cytokines, impaired activation of vitamin D, and elevated procalcitonin are contributory.

It remains unclear whether sepsis-induced hypocalcemia is pathologic or protective. Calcium administration in experimental sepsis has been shown to increase or have no effect on mortality.^{21,22} Similarly, investigations on the effects of Ca^{2+} blockade on septic mortality demonstrate conflicting results.²³⁻²⁵ Therefore, although sepsis-induced hypocalcemia is commonly seen in critically ill patients, neither routine replacement of calcium nor the use of calcium channel blockers is supported by the existing literature. As with most situations, sepsis-induced hypocalcemia should be treated if patients are symptomatic.

Pancreatitis represents another inflammatory condition that is associated with hypocalcemia in critically ill patients.^{1,3,25,26} Saponification of retroperitoneal fat contributes to the development of hypocalcemia in patients with pancreatitis.^{3,25,26} In rats with experimental pancreatitis, injection of free fatty acids into the peritoneum induces hypocalcemia.²⁵ However, the amount of calcium chelated is relatively small compared to the calcium stores in the bone reservoir available for exchange. Interestingly, elevated levels of PTH seen in pancreatitis, like sepsis, do not result in normalized ionized calcium levels.²⁵⁻²⁷ Although the resistance of bone and kidney to PTH may be a factor, it is likely that inflammatory pathways identical to those in sepsis are responsible. In pancreatitis, like sepsis, hypocalcemia is an indicator of disease severity. As with most clinical conditions, calcium replacement during pancreatitis should be reserved for the symptomatic or hemodynamically unstable patient.

SIGNS AND SYMPTOMS OF HYPOCALCEMIA

Hypocalcemia is frequently asymptomatic and attributable signs or symptoms may be difficult to elucidate in critically ill patients. In general, the signs and symptoms of hypocalcemia correlate with both the magnitude and rapidity of onset of the condition. Neurologic (paresthesias, seizures, dementia) and cardiovascular (hypotension, impaired cardiac contractility, dysrhythmias) signs may be seen with ionized hypocalcemia $\text{Ca}^{2+} < 1.0$ mmol/L.^{3,5} Neuromuscular symptoms of profound hypocalcemia include muscle spasms and tetany. Psychiatric disturbances (dementia, psychosis, depression) also may be attributable to hypocalcemia.^{3,5}

Classic signs of hypocalcemia include the Chvostek and Trousseau signs, which test for latent tetany. The Chvostek sign is an involuntary twitching of facial muscles in response to light tapping of the facial nerve. It is nonspecific and is present in 10% to 25% of normal adults, and may be completely absent in chronic hypocalcemia. The Trousseau sign is a carpal spasm induced by reduced blood flow to the hand in the presence of hypocalcemia when a blood pressure cuff is inflated to 20 mmHg for 3 min. The Trousseau sign is also nonspecific and may be absent in one-third of patients with hypocalcemia.

Cardiac dysrhythmias, such as ventricular tachycardia, prolonged QT interval, and heart block are more serious complications of hypocalcemia.^{3,5} In addition, decreased cardiac output and hypotension, especially where refractory to vasopressors and volume, should prompt calcium replacement when hypocalcemia is present.^{3,5}

TREATMENT OF HYPOCALCEMIA

Critical thresholds for calcium replacement vary, but severe ionized hypocalcemia < 0.8 mmol/L and symptomatic hypocalcemia should be replaced in critically ill patients.^{1,3,5} Treatment of asymptomatic ionized hypocalcemia > 0.8 mmol/L is usually unnecessary and may be potentially harmful in conditions such as sepsis and cellular hypoxia.^{1,3,5,27}

Treatment of hypocalcemia requires intravenous calcium replacement. The two solutions most commonly used are 10% calcium chloride and 10% calcium gluconate. Each solution contains 100 mg/mL of calcium salt and is provided in 10-mL ampules. Ten percent calcium chloride contains 27 mg/mL of elemental calcium (1.36 mEq/mL); 10% calcium gluconate contains 9 mg/mL (0.46 mEq/mL). Typically, 10 mL of 10% calcium gluconate solution is infused over 10 min. A total of 200 mg of elemental calcium may be necessary to raise the total serum calcium by 1 mg/dL. Since the effect of calcium infusion is usually brief, a continuous infusion may be necessary. Calcium chloride should not be infused peripherally if calcium gluconate is available, since the former can produce tissue necrosis and thrombophlebitis if extravasation occurs.

Hemodynamically unstable patients in the ICU who are hypocalcemic may show a transient increase in blood pressure and/or cardiac output with calcium administration. This is probably due to increased cardiac performance.²⁷ However, in the presence of tissue hypoxia, calcium administration may aggravate the cellular injury.^{9,24} Nonetheless, calcium administration is probably warranted in the hypocalcemic, hemodynamically unstable patient, especially those requiring adrenergic support.

Despite the prevalence of hypocalcemia in critically ill patients, there is a paucity of evidence on the benefit of calcium supplementation in this population. Other than elevating systemic ionized calcium, there is no clear evidence that calcium supplementation impacts the outcome in critically ill ICU patients.²⁸ Collectively, these data suggest that hypocalcemia is a metabolic derangement associated with severe illness as opposed to a correctable condition resulting in a poor outcome.

HYPERCALCEMIA

Hypercalcemia is rare in critically ill patients, estimated to be present in between 1% and 15% of ICU patients.² Defined as an increase in serum calcium above 10.4 mg/dL (2.60 mmol/L), hypercalcemia usually is caused by excessive bone resorption. Hyperparathyroidism and humoral hypercalcemia of malignancy are the most common causes of hypercalcemia in hospitalized patients.^{2,5,29} Less common causes of hypercalcemia include sarcoidosis, prolonged immobilization, and medications (e.g., thiazide diuretics).

Mild hypercalcemia is usually asymptomatic. However, patients with circulating Ca^{2+} above 12 mg/dL may manifest symptoms of confusion, delirium, psychosis, and coma.^{2,5,29} Patients with hypercalcemia also may experience nausea, vomiting, constipation, abdominal pain and ileus. Cardiovascular effects of hypercalcemia include hypotension, hypovolemia, and shortened QT interval. Profound skeletal muscle weakness may result. Seizures, however, are rare.

The treatment of hypercalcemia should be directed at the underlying medical condition. Saline infusion and diuresis are indicated in symptomatic patients and when the serum calcium level rises above 14 mg/dL (3.5 mmol/L). For patients with underlying malignancy, treatment with salmon calcitonin, pamidronate, or plicamycin may be necessary. These agents act to inhibit bone resorption. Hydrocortisone can also be used in combination with calcitonin to treat hypercalcemia associated with multiple myeloma.

Hypoglycemia is associated with increased mortality in critically ill patients.^{1,2} The single largest factor limiting the achievement of adequate glycemic control in the intensive care unit (ICU) is the occurrence of hypoglycemia and the consequent increase in mortality. This chapter will discuss the definitions of hypoglycemia, its incidence, risk factors, physiology, symptomatology, evaluation, outcomes, and management.

■ DEFINITION OF HYPOGLYCEMIA

Traditionally, the American Diabetes Association (ADA) has defined hypoglycemia in five categories³:

- Severe hypoglycemia (symptoms requiring assistance from another person, neuroglycopenic symptoms, seizures or coma, and reversal of these symptoms with the administration of glucose). Glucose measurements may not be available, but neurologic recovery after glucose administration is diagnostic.
- Documented symptomatic hypoglycemia (with a measured plasma glucose of <70 mg/dL [3.9 mmol/L]).
- Asymptomatic hypoglycemia (no symptoms of hypoglycemia but measured plasma glucose is <70 mg/dL [3.9 mmol/L]).
- Probable symptomatic hypoglycemia (symptoms of hypoglycemia not accompanied by a plasma glucose measurement but are presumed to be caused by a plasma glucose concentration <70 mg/dL [3.9 mmol/L]);
- Relative hypoglycemia (symptoms of hypoglycemia in a person with diabetes but with a measured plasma glucose concentration >70 mg/dL [3.9 mmol/L]).

The definition of hypoglycemia in a critically ill patient is challenging because of a lack of symptom reporting in sedated or critically ill patients. The definition and recognition of hypoglycemia in this group of patients is dependent on close monitoring of measured blood glucose. Landmark studies, which have resulted in current glucose management strategies in the ICU, have repeatedly used previously defined severe hypoglycemia values (blood glucose <40 mg/dL [2.2 mmol/L]) for the diagnosis of hypoglycemia in the ICU.^{4,6}

Likewise, the ADA in 2016 defined hypoglycemia as follows⁷:
Moderate hypoglycemia: 40–70 mg/dL (2.2–3.9 mmol/L)
Severe hypoglycemia: <40 mg/dL (2.2 mmol/L).

■ INCIDENCE OF HYPOGLYCEMIA IN THE CRITICALLY ILL

The reported incidence of hypoglycemia is variable and depends on the definition used, the glycemic target, and the admission diagnosis. In a retrospective study conducted by Bagshaw et al. from the Australia New Zealand Intensive Care Society adult patient database, the incidence of hypoglycemia (lowest blood sugar observed during the first 24 hours of ICU stay) ranged from 1.5% to 13.8% depending on the definition used (<82 mg/dL [4.5 mmol/L] versus <44 mg/dL [2.4 mmol/L]).⁸

An interesting study by Niven et al. examined the impact of two major landmark trials (Leuven 1 and NICE-SUGAR) on glycemic management in 195 adult ICUs over 80 hospitals from January 1, 2001, to December 31, 2012, using the APACHE database. At the start of the study the incidence of hypoglycemia was 3%. This increased to 5.8% after the Leuven study, which advocated tight glycemic control, was published and then slightly dropped to 5.2% after the NICE-SUGAR

investigators published their results recommending a more liberal target.⁹

■ THE GLYCEMIC DOMAINS AND THE INFLUENCE OF PREEXISTING DIABETES DIAGNOSIS ON OUTCOMES IN THE ICU

The three domains of glycemic control are hyperglycemia, hypoglycemia, and glucose variability. Each of these has independently been shown to increase mortality in critically ill patients.^{2,10–13} Two large studies evaluated these three domains and the approach to glycemic management in the ICU, as well as the role of diabetes in this complex milieu. The results of both studies are strikingly similar. Hyperglycemia and an increase in glucose variability were associated with an increase in mortality in nondiabetic but not in diabetic patients. On the other hand, hypoglycemia was associated with an increase in mortality in both groups. Furthermore, in diabetic patients, premonitory glycemic control has been shown to play an important role in outcomes based on the glycemic goals. In patients with poor preadmission glycemic control, mortality was higher with lower ICU blood glucose levels (than their own “normal”—i.e., relative hypoglycemia). Conversely, in patients with good preadmission glycemic control, survival was higher when ICU blood glucose levels were maintained closer to the normal range. Plummer et al. in 2014¹⁴ further substantiated previous observations by Egi et al.¹⁵ in their study where they observed an 18% increase in the risk of mortality for every 20 mg/dL (1.1 mmol/L) increase in maximum blood glucose in nondiabetic and diabetic patients with good preadmission glycemic control. The data from these studies further emphasizes that having one glycemic goal for all critically ill patients is probably not appropriate.^{14–17}

■ GLYCEMIC GOAL IN THE ICU

Based on the NICE-SUGAR trial, most centers target a blood glucose level of <180 mg/dL (10 mmol/L) for critically ill patients in an attempt to reduce the incidence of hypoglycemia and subsequent mortality⁶ noticed with the application of tight glycemic control. The ADA also recommends a goal of 140–180 mg/dL (7.7–10 mmol/L) in ICU patients.⁷

■ MEASUREMENT OF BLOOD GLUCOSE IN THE ICU

Most ICUs use point-of-care (POC) glucometers to determine blood glucose concentration. The accuracy of these glucometers, measurements of capillary blood glucose, and the titration of insulin infusions based on these values has been questioned. Several factors that are commonly present in critically ill patients, like anemia, hypoxia, medications, and acidosis, may lead to POC glucometer inaccuracy. Furthermore, these patients may be significantly volume overloaded, and capillary blood glucose may not reflect the whole blood glucose concentration accurately. Laboratory whole blood glucose is the gold standard for blood glucose measurement. Nevertheless, it is labor-intensive, time-consuming, and costly and thus not practical when hourly blood glucose concentrations need to be monitored. Hence glucometers have been used widely in ICUs for this purpose. Arterial whole blood samples drawn via the arterial line using a blood gas analyzer (BGA) have been found to be associated with fewer errors (1% outside the allowed 20% error zone) when compared to capillary samples (27%

outside the 20% error zone) or arterial samples (12% outside the 20% error zone) using a glucometer.¹⁸ Arterial blood samples have thus been recommended for measurement of blood glucose using a BGA, and this has also been extended to POC testing when used, as opposed to capillary blood samples. Since the inaccuracies of POC testing are more pronounced in the hypoglycemic range, it may be prudent to confirm the blood glucose concentration using another method when near the hypoglycemic range.

Due to the high incidence of dysglycemic episodes in the ICU, continuous glucose monitoring (CGM) techniques are being pursued as the potential future method to consistently recognize dysglycemic and hypoglycemic episodes. CGM techniques could be either subcutaneous or intravenous and have proven to be as effective and safe as POC techniques, reducing nursing burden and detecting more dysglycemic/hypoglycemic episodes, especially during the night, as compared to POC testing.¹⁹⁻²¹ Although promising, the routine use of CGM in ICUs would need more trials demonstrating their safety and efficacy.⁷

RISK FACTORS AND BARRIERS TO RECOGNITION OF HYPOGLYCEMIA IN THE ICU

Identified predictors of hypoglycemia in the ICU include female gender, APACHE 2 score, continuous veno-venous hemodialysis (CVVHD), use of bicarbonate substitution solutions, diagnosis of sepsis, use of vasopressors/inotropes, prior diagnosis of diabetes mellitus, serum creatinine >3 mg/dL, insulin therapy, discontinuation of nutrition therapy without an adjustment in insulin therapy, mechanical ventilation, and ICU length of stay.²²⁻²⁴ There are several barriers to the recognition of hypoglycemia in a critically ill patient—sedation, absence of symptoms, reduced oral intake, frequent change in rate of enteral or parenteral nutrition, and inappropriate timing of insulin. Even a single episode of severe hypoglycemia (<45 mg/dL [2.5 mmol/L]) has been associated with increased mortality.²⁴ Increased vigilance and relaxation of the glycemic target is warranted in patients with risk factors so as to reduce the incidence of hypoglycemia.

OUTCOMES OF HYPOGLYCEMIA IN THE CRITICALLY ILL

In a post hoc analysis of the NICE-SUGAR trial, severe hypoglycemia (<40 mg/dL [2.2 mmol/L]) and moderate hypoglycemia (41-70 mg/dL [2.3-3.9 mmol/L]) occurred in 3.7% and 45% of the studied patients, respectively. Although hypoglycemia was more common in the intensive insulin therapy group (93.3% severe hypoglycemia; 82.4% moderate hypoglycemia), the association of hypoglycemia with death was similar in both groups. Moderate hypoglycemia was associated with a 40% increase in the risk of death, and severe hypoglycemia doubled this risk. For both groups, the strongest association with death was from distributive shock. This was probably related to impairment of autonomic function, white cell activation, and release of inflammatory mediators.²⁵ In a recent systematic review and meta-analysis of longitudinal follow-up cohort studies investigating the association between hypoglycemia and adverse outcomes, a dose-dependent relationship between the severity of hypoglycemia and adverse vascular events, and mortality was found.²⁶ In some circumstances, hypoglycemia is a consequence of severe underlying disease and serves as a marker of death and not necessarily the cause. From prospectively collected data from two observational cohorts, patients with hypoglycemia had a higher mortality in comparison with those without hypoglycemia, even after stratification by severity of illness, diagnostic category, diabetic status, mean blood glucose during ICU admission, and coefficient of variation as an index of glycemic variability.¹³ In a retrospective cohort study from the Netherlands, Hermanides et al. corrected for the severity of disease using the SOFA (Sequential Organ Failure Assessment) score and in spite of the adjustment for disease severity, the incidence of death in patients exposed to hypoglycemia (<45 mg/dL [2.5 mmol/L]) was 40 per 1000 ICU days

compared to 17 per 1000 ICU days in patients without an exposure to hypoglycemia, indicating a possible causal relationship.²⁷

PHYSIOLOGY AND SYMPTOMATOLOGY OF HYPOGLYCEMIA

During an episode of hypoglycemia, below a blood glucose concentration of 65 mg/dL (3.6 mmol/L), the secretion of counter regulatory hormones, glucagon and epinephrine, increases. Both glucagon and epinephrine increase blood glucose concentrations by increasing gluconeogenesis and glycogenolysis, glucagon to a much greater degree than epinephrine. Free fatty acids are mobilized from the adipose tissue and converted to ketone bodies to be utilized as an energy source when there is a decrease both in insulin and in the ratio of insulin to glucagon.²⁸ The brain and heart are two organs that are dependent on glucose for energy utilization and function. Consequently, most of the symptoms of hypoglycemia are related to these two organ systems.

The brain utilizes glucose and ketone bodies as fuel, especially during starvation.²⁹ Brain glucose concentrations drop close to zero when blood glucose concentration falls below 36 mg/dL (2 mmol/L). This can result in irreversible brain injury in cases of severe and prolonged hypoglycemia.³⁰ Patients experiencing hypoglycemia present with either adrenergic (tremors, palpitations, anxiety), cholinergic (sweating, paresthesias), or neuroglycopenic symptoms (cognitive, behavioral, psychomotor changes, seizures, coma).³¹⁻³³ Hypoglycemic coma may occur when glucose levels are below 40-50 mg/dL (2.2-2.3 mmol/L).³³ The neurons most sensitive to hypoglycemia are located in the superficial layers of the cortex, the hippocampus, the caudate nucleus, and the subiculum.^{28,34,35} Even in the absence of cell death, mild recurrent hypoglycemia can cause dysfunction in the hippocampus.³⁶

The myocardial cells can utilize either fatty acids or glucose as fuel. During episodes of hypoxia or ischemia, myocardial cells preferentially use glucose as substrate for ATP generation.³⁷ Hypoglycemic episodes stimulate the sympathoadrenal system, which can be proarrhythmic.³⁸ Various rate and rhythm disturbances including sinus tachycardia, sinus bradycardia, atrial and ventricular ectopics, and ventricular repolarization abnormalities have been observed during acute hypoglycemic episodes.³⁹⁻⁴¹

MANAGEMENT OF HYPOGLYCEMIA

Management of hypoglycemia involves recognition, development of a differential diagnosis and treatment.

Recognition of Hypoglycemia (Fig. 18-1)

- Hypoglycemia is usually recognized using the Whipple's triad: symptoms of hypoglycemia, documented low blood glucose concentration, and resolution of symptoms when plasma glucose is raised. This is not always possible in critically ill patients. The diagnosis of hypoglycemia is established when the measured plasma glucose is less than 70 mg/dL (3.9 mmol/L).

Differential Diagnosis

- In a critically ill patient, hypoglycemia may be a consequence of therapy with insulin for the management of hyperglycemia, especially when there is a change in nutritional support. Other insulin secretagogues, oral hypoglycemic agents, and several other non-antihyperglycemic agents⁴² are frequent culprits as well. The commonly cited nonantihyperglycemic drugs responsible for inducing hypoglycemia are quinolones, pentamidine, quinine, beta blockers, angiotensin converting enzyme (ACE) inhibitors, and insulin-like growth factor (IGF).⁴² Critical illness or sepsis leading to hepatic, renal and cardiac dysfunction in and by itself can cause hypoglycemia. Rarely tumors (islet and non-islet cell), hormonal deficiencies and development of antibodies to either insulin or the insulin receptor may be the cause of hypoglycemia in critically ill patients.⁴³

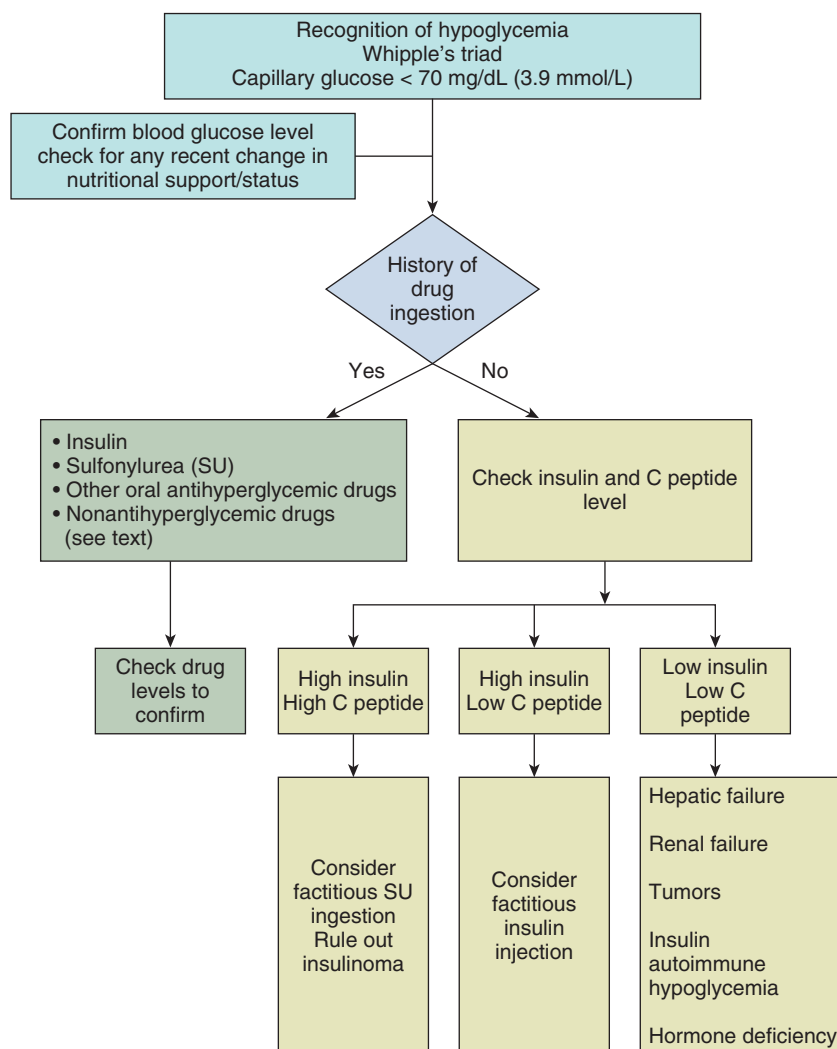

FIGURE 18-1 ■ Recognition and evaluation of hypoglycemia.

Evaluation

- When blood glucose concentration is indicative of hypoglycemia, if there is no obvious medication-related cause, measurement of insulin and C peptide levels can be helpful.
- Make sure that no sudden change in nutritional status has been made (nil per oral (NPO) status/change in rate of enteral/parenteral feed).
- If sulfonylurea is suspected as the cause, radioimmunoassay can detect sulfonylurea levels.
- Check all medications to look for medication-induced hypoglycemia (nonantihyperglycemic).
- Evaluate for deterioration in renal or hepatic function.
- Evaluate for hormonal deficiencies: thyroid hormone, cortisol.

Management (Fig. 18-2)

- Depending on the extent of neurologic or neuroglycopenic symptoms, make sure that airway protection is ensured.
- Supplementing glucose is paramount once a diagnosis of hypoglycemia is established. Patients with mild to moderate symptoms of hypoglycemia are effectively treated with oral glucose tablets or carbohydrate-rich food supplements. A response is usually seen in 15-20 minutes. Continued monitoring and supplementation with glucose (as needed) is recommended as the response to oral glucose may be transient.^{43,44}

- In patients who have severe symptoms or are unable to take glucose orally, intravenous dextrose is supplemented. An initial dose of 25 g of 50% dextrose is given. Similar to oral glucose, the effect is transient and may need a continuous dextrose infusion.
- Glucagon can either be given intravenously or subcutaneously at a dose of 1 mg in adults when hypoglycemia is severe or refractory. This can cause transient hyperglycemia.⁴⁴
- Depending on the cause, an extended period of treatment may be necessary such as in the case of sulfonylurea-induced hypoglycemia or inadvertent administration of a large dose of insulin.
- In cases of sulfonylurea-induced hypoglycemia, octreotide may be used.⁴⁵⁻⁴⁷

CONCLUSION

Although glycemic control and avoidance of hyperglycemia is important in critically ill patients, very close attention should be paid to prevent hypoglycemia and its related adverse outcomes. Hypoglycemia is more detrimental than hyperglycemia. Even mild hypoglycemia in the critically ill is associated with increased mortality.¹³ An association has been found between the adoption of tight glucose control strategies in the ICU and the development of hypoglycemia. Current evidence suggests moving toward more moderate targets that have been shown to improve outcomes and are associated with fewer hypoglycemic episodes, until further evidence emerges.

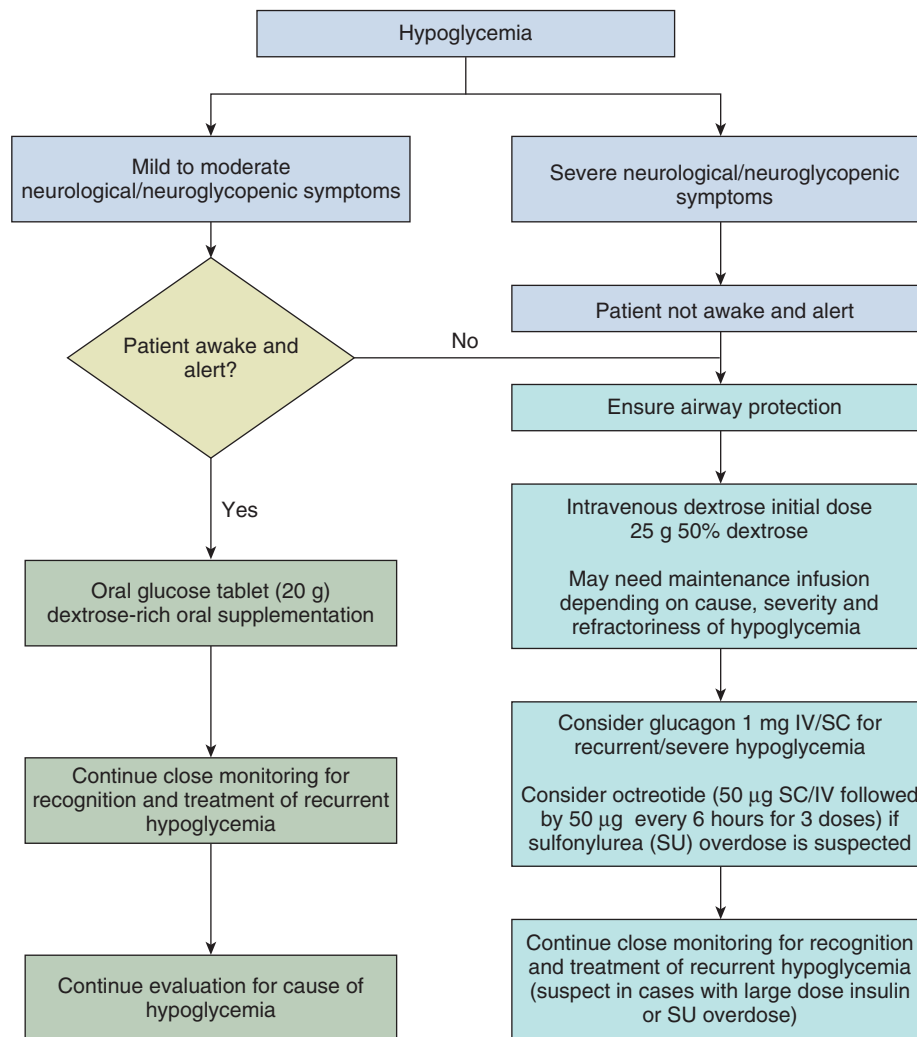

FIGURE 18-2 ■ Management of hypoglycemia.

KEY POINTS

1. Hypoglycemia, and the subsequent increase in mortality, is the single largest factor limiting achievement of glycemic control in the ICU.
2. ADA defines moderate hypoglycemia as a blood glucose level of 40-70 mg/dL (2.2-3.9 mmol/L) and severe hypoglycemia as a blood glucose < 40 mg/dL (2.2 mmol/L).
3. Mild, moderate and severe hypoglycemia are associated with increased mortality in the critically ill and any blood sugar less than 70 mg/dL (3.9 mmol/L) warrants aggressive evaluation and management.
4. The ADA standards of medical practice 2016 recommend a goal of 140-180 mg/dL (7.7-10 mmol/L) in critically ill patients although the goal may vary from patient to patient based on the admission diagnosis, a preadmission diagnosis of diabetes, and chronic glycemic state.
5. Although laboratory whole blood glucose is the gold standard for blood glucose measurement, it is time-consuming, labor-intensive, and thus not practical when hourly blood glucose measurements are required. Hence measurements using arterial blood samples via the arterial line (vs. capillary blood) utilizing preferably a BGA or a POCT have been successful.
6. Identified predictors of hypoglycemia in the ICU include female gender, APACHE 2 score, CVVHD, use of bicarbonate substitution solutions, diagnosis of sepsis, use of vasopressors/inotropes, prior diagnosis of diabetes mellitus, serum creatinine > 3 mg/dL, insulin therapy, discontinuation of nutrition therapy without an adjustment in insulin therapy, mechanical ventilation, and ICU length of stay.
7. Patients experiencing hypoglycemia present with either adrenergic (tremors, palpitations, anxiety), cholinergic (sweating, paresthesias), or neuroglycopenic symptoms (cognitive, behavioral, psychomotor changes, seizures, coma). Various heart rate and rhythm disturbances have also been observed during acute hypoglycemic episodes.
8. Once hypoglycemia is recognized, various possible causes should be evaluated and immediate management initiated. Depending on the cause, an extended duration of treatment may be required.

This study done by the NICE-SUGAR investigators is a post-hoc analysis of the original study done in 2009 that showed that intensive glucose therapy in critically ill patients posed an increased risk of death in addition to an increased incidence of hypoglycemia. With this analysis they demonstrated that, although not causal, both moderate and severe hypoglycemia was associated with an increased risk of death.

Krinsley JS, Schultz MJ, Spronk PE, Harmsen RE, van Braam Houckgeest F, et al. Mild hypoglycemia is independently associated with increased mortality in the critically ill. *Crit Care* 2011;15:R173.

This paper reports the results of the analysis of data from an international cohort of patients (N=6240). They found a significantly increased risk of death with even mild hypoglycemia in critically ill patients.

American Diabetes Association. 13. Diabetes Care in the Hospital. *Diabetes Care* 2016;39(Suppl 1):S99-S104.

Hyperglycemia is by far the most common metabolic abnormality in the intensive care unit. The adverse effects of uncontrolled hyperglycemia, especially in a critically ill patient, are fairly well described.¹⁻³ The management of hyperglycemia in the critically ill patient has gone through substantial changes over the past decade. Although hyperglycemia is associated with adverse clinical outcomes, trying to achieve euglycemia may not be the solution. While the initial landmark randomized controlled trial showed remarkable benefits to tight glycemic management in the intensive care unit (ICU),¹ a somewhat similar strategy did not improve clinical outcomes. On the contrary, it resulted in an increase in hypoglycemic episodes and consequently mortality according to the largest multicenter randomized controlled trial to date.^{4,5} It is worth noting that there is an exceedingly large body of evidence from observational and retrospective studies shedding light on the various glycemic domains that clinicians should keep in mind while achieving glycemic control.⁶⁻⁸ The presence or lack of a history of diabetes and extent of a patient's chronic glycemic state if they were diabetic would probably play a role in determining the glycemic target.^{9,10} Furthermore, glycemic variability of whatever target is chosen may also have an impact on glycemic management outcomes.¹¹

This chapter gives an overview of hyperglycemia in the critically ill patient and current management strategies, including a summary of investigations that led to the development of these strategies.

DEFINITION OF HYPERGLYCEMIA

When a critically ill patient is hyperglycemic, it is important to delineate the clinical group to which the patient belongs. These include the following:

- A known diabetic
- Undiagnosed diabetic
- New-onset hyperglycemia (stress-induced)

The American Diabetes Association has published criteria for the diagnosis of diabetes mellitus.¹² A diagnosis of diabetes is established when any one of the following criteria is met:

- Fasting plasma glucose greater than 126 mg/dL (7 mmol/L)
- Postprandial plasma glucose >200 mg/dL (11.1 mmol/L) after 2 hours of a 75-g glucose oral glucose tolerance test
- HbA1C >6.5%
- Classic symptoms of hyperglycemic crisis with a random glucose >200 mg/dL (11.1 mmol/L)

Unfortunately, there is no set definition for hyperglycemia in the critically ill patient as it is confounded by the presence of multiple variables including the severity of illness, concurrent medication such as catecholamine infusions, feeding, etc. When a patient presents with new-onset hyperglycemia (NOH), either critically or noncritically ill, it is prudent to rule out the presence of undiagnosed diabetes mellitus. The presence of an HbA1C >6.5% might aid in making this diagnosis. The ADA/ACCE in their consensus statement recommend that any blood glucose >180 mg/dL (10 mmol/L) be treated in patients who are critically ill in an attempt to reduce the adverse outcomes associated with hyperglycemia.¹³

STRESS-INDUCED HYPERGLYCEMIA

Hyperglycemia was initially considered to be a normal adaptive response in a critically ill patient to survive a period of acute stress. An increase in the levels of catecholamines, growth hormone, exogenous and endogenous glucocorticoids and glucagon, along with an increase in circulating cytokines and peripheral insulin resistance, may play an important role in the genesis of stress-induced hyperglycemia.^{14,15} However, stress hyperglycemia in the presence of previously normal glucose homeostasis has been associated with an increase in adverse outcomes in critically ill patients. These adverse outcomes were attributed to hyperglycemia per se and/or free radical injury and its related adverse coronary and intracranial events.¹⁶ That being said, hyperglycemia during acute illness may not be the causative agent behind the increase in morbidity and mortality but rather only represents a correlation with disease severity.

DIABETIC VERSUS NON-DIABETIC BLOOD GLUCOSE MANAGEMENT IN THE ICU

Recently, it has been advocated that glycemic targets in the ICU should probably vary based on the presence of a history of diabetes and a chronic glycemic state prior to ICU admission.^{6,9,10,17,18} The diabetic patient can probably tolerate or might even do better with a higher-than-normal glycemic target and reduced glycemic variability. Egi et al. studied 450 critically ill diabetic patients, with a total of 9946 glucose measurements in the study cohort. The median HbA1C was 7%. They found that patients who had higher (>7%) preadmission HbA1C levels had a lower mortality when the ICU time-weighted glucose concentration was higher (>180 mg/dL [10 mmol/L]), as compared to patients who had lower HbA1C (<7%).¹⁹ Similar findings were reported in larger patient cohorts.^{9,20,21} In 2012, Tayek et al. performed a meta-analysis of nine studies with regard to hyperglycemia and in-hospital mortality, measuring unadjusted ICU mortality in five of the nine studies. They observed an increase in ICU mortality and a 2.7-fold increase in hospital mortality in patients with new-onset hyperglycemia as opposed to diabetic patients with hyperglycemia.²² This difference may be due to the fact that in a previously uncontrolled diabetic, the organs and immune system may have been accustomed to higher blood glucose concentrations, and a sudden attempt at euglycemia will represent a relative hypoglycemia for them. Furthermore, if such an attempt at euglycemia is associated with moderate or severe hypoglycemia as is the case with many tight glycemic control algorithms, such dangerously low concentrations would also represent a significant increase in glycemic variability that is thought to be harmful as well.¹¹ In one of the largest database studies evaluating the effect of diabetes on outcomes in critically ill patients, Graham et al. found that hyperglycemia was more detrimental in nondiabetics and was potentially protective in diabetics. There was an increased risk of mortality exclusively in diabetic patients in the normoglycemic/hypoglycemic

glucose range suggesting a relative intolerance to relative and absolute hypoglycemia in this subset of patients.²³ In light of these findings, we probably should seek different glycemic targets (and more robust insulin protocols to achieve such targets) that vary based on the presence of a diagnosis of diabetes and previous chronic glycemic states. An example of such variable glycemic targets has recently been proposed by Marik et al. based on the patient's clinical condition, history of diabetes, and HbA1C signifying the extent of glycemic control.²⁴

LANDMARK INVESTIGATIONS STUDYING HYPERGLYCEMIA IN THE CRITICALLY ILL PATIENT

The Leuven 1 Trial, Surgical ICU, 2001¹

One of the first investigators to research into the field of hyperglycemia and its management in critically ill patients were Van Den Berghe and colleagues from Leuven, Belgium. This was a landmark study which brought about a significant practice change at that time, or at least raised an important question for which researchers were seeking answers.

The study involved 1548 surgical ICU patients of whom 63% were routine cardiac surgical patients. They were randomized to either intensive insulin therapy (IIT) (80-100 mg/dL [4.4-5.5 mmol/L]) or conventional (180-200 mg/dL [10-11.1 mmol/L]) glucose management. Interestingly, both groups received 200 mg of glucose on postoperative day 1 followed by nutrition either enteral or parenteral, started on postoperative day 2. Total parenteral nutrition was initiated on postoperative day 2 if enteral nutrition was found to be inadequate. In hindsight, this probably played a big role in most of the results that were generated. Their results were significant and resulted in a practice change in ICUs across the globe given the mortality benefit of the suggested regimen:

- As expected, mean glucose levels were lower in the IIT group compared to the conventional group; however, hypoglycemia was seen more often in the IIT group.
- ICU and hospital mortality were lower in the IIT group as compared to the conventional management group (4.6% vs. 8% and 7.2% vs. 10.9%, respectively).
- Decreased critical illness, polyneuropathy, acute kidney injury (AKI), and transfusion requirements were observed in the IIT group.

The Leuven II Trial Medical ICU Patients, 2006²

The same investigators from the Leuven I trial studied the effects of IIT versus conventional management in medical ICU patients through a randomized controlled trial. They randomized 1200 patients to either IIT or conventional therapy. Again, as expected, there was an increase in the occurrence of hypoglycemia in the IIT group. They found that IIT did not alter hospital mortality but there was a reduction in ICU length of stay, mechanical ventilation, and AKI.

The VISEP Trial, 2008²⁵

In a multicenter trial from Germany, patients with severe sepsis were assigned to receive either IIT to maintain a blood sugar of 80 to 100 mg/dL (4.4-5.5 mmol/L), or conventional insulin therapy to maintain a blood sugar of 180 to 200 mg/dL (10-11.1 mmol/L). They randomized patients to receive 10% hetastarch, a low-molecular-weight hydroxyethyl starch (HES), or lactated Ringer's solution as the resuscitation fluid. Primary end points were death at 28 days and mean organ failure scores. This trial had to be terminated prematurely due to the unacceptably higher incidence of severe hypoglycemia (<40 mg/dL) (17% vs. 4.1%) and serious adverse events (10.9% vs. 5.2%) in the IIT group as compared to conventional therapy. They also found that HES therapy was associated with a higher incidence of acute renal

failure and renal replacement therapy compared to lactated Ringer's therapy.

The Glucontrol Trial, 2009²⁶

This was a prospective randomized controlled trial to evaluate the effects of IIT versus moderate glucose control on ICU mortality. Patients were randomly assigned to either group 1 (target blood glucose 140-180 mg/dL [7.8-10 mmol/L]) or to group 2 (target blood glucose approximately 80-110 mg/dL [4.4-6.1 mmol/L]). This study had to be terminated prematurely due to an unacceptable number of protocol violations. Nevertheless, the major finding from this study was a lack of clinical benefit, and an increased incidence of hypoglycemia (8.7% in group 2 vs. 2.7% in group 1) in the IIT group as compared to the intermediate glucose control group.

NICE-SUGAR Trial, 2009⁴

This is the largest multinational randomized trial comparing IIT (target blood sugar 81-108 mg/dL [4.5-6 mmol/L]) to moderate target (less than 180 mg/dL [10 mmol/L]) in critically ill adult patients. The primary end point was death due to any cause within 90 days of randomization. There was an increased incidence of mortality in the IIT group (27.5%; odds ratio 1.14), as compared to the conventional group (24.9%). There was no difference in mortality between surgical and nonsurgical patients. Similar to prior studies, the incidence of severe hypoglycemia (<40 mg/dL [2.2 mmol/L]) was higher (6.8%) in the IIT group as compared to the conventional group (0.5%). They concluded that intensive glucose control increased mortality among critically ill adult patients and that a blood glucose target of 180 mg/dL (10 mmol/L) or less would result in lesser mortality.

The COITSS Trial, 2010²⁷

This multicenter randomized controlled trial was done to test the efficacy of IIT in patients with septic shock who were being treated with hydrocortisone and also to assess the benefit of fludrocortisone in these patients. They concluded that there was no mortality benefit in using IIT and tight glucose control in patients with septic shock. The mortality rate in the IIT group was 45.9% versus 42.9% in the conventional group ($P = 0.50$). Of the patients receiving IIT, 16.4% experienced severe hypoglycemia versus 7.8% in the conventional group ($P = 0.003$), which was significant.

GLUCOSE MONITORING IN THE ICU

In current day practice, most ICUs use bedside glucometers for monitoring, reporting, and managing blood glucose in critically ill patients. Bedside glucometers were introduced in an attempt to improve outpatient diabetes control (i.e., for patient self-monitoring of blood glucose). They are probably not very accurate for intensive monitoring and treatment of hyperglycemia in critically ill patients.²⁸⁻³¹ There are multiple variables that can affect the accuracy of a bedside glucometer, such as rapidly changing hematocrit, hypoxia, acidosis, use of vasopressors, and peripheral edema, which make measuring capillary blood glucose using a bedside glucometer less than ideal in the monitoring of patients who need titration of insulin infusions. The Central Laboratory and Standards Institute (CLSI), and the FDA require that 95% of the meter readings are within 20% of the reference value. While such monitors may meet this standard, the issue remains that allowing even that much of a variation in a critically ill patient on an infusion can lead to dangerous insulin therapy.³¹ Laboratory whole blood glucose measurement is the gold standard in blood glucose measurement but is labor intensive and not very practical when hourly glucose measurements are required. Another option is to monitor blood glucose using a blood gas analyzer (BGA), which is close to laboratory standards.³⁰ Blood glucose measurement from arterial whole blood samples drawn via an arterial line using a BGA is associated with fewer

errors (1% outside the permitted 20% error zone) when compared to capillary samples (27% outside the 20% error zone) or arterial samples (12% outside the 20% error zone) using a glucometer.³² Arterial blood samples have been recommended for the measurement of blood glucose using a BGA, and this has also been extended to point-of-care (POC) testing when used, as opposed to capillary blood samples. In critically ill patients who are dysglycemic, hourly blood glucose measurements are recommended.³³ Although POC testing has been largely used for this purpose, there are continuous glucose monitoring (CGM) techniques being developed to consistently recognize dysglycemic episodes.³⁴ CGM techniques could be either subcutaneous or intravenous. Subcutaneous CGM devices have been studied more extensively. The accuracy and reliability of these subcutaneous devices have been demonstrated in critically ill patients in circulatory shock and on vasopressor infusions.³⁵ In a randomized trial evaluating the impact of CGM on glycemic control and the occurrence of hypoglycemia in critically ill patients, CGM did not improve overall glycemic control but did reduce the occurrence of hypoglycemic events.³⁶ Another interesting extension of CGM is in the implementation of fully automated closed-loop glucose control. This system automatically modulates insulin (or dextrose) delivery based on glucose measurements using a CGM device without nurse input. Leelarathna et al. evaluated the feasibility of an automated closed-loop glucose control system using continuous subcutaneous glucose measurements in critically ill patients and were able to demonstrate an increased duration in the target range without the occurrence of hypoglycemia.³⁷ CGM techniques are probably as effective and safe as POC testing. In addition, they reduce nursing burden and detect more dysglycemic/hypoglycemic episodes, especially during the night.^{36,38,39} Although the technology seems very promising, routine use of CGM techniques in ICUs would need more trials demonstrating their safety and efficacy.⁴⁰

Irrespective of the method of blood glucose monitoring or target blood glucose used, there is a requirement to implement a systematic algorithm for insulin infusion titration in the critically ill patient to reduce the occurrence of adverse incidents, primarily hypoglycemia and glucose variability, as suggested by Preiser et al.^{41,42} Although this was suggested at a time when tight glucose control was still in vogue, it still holds true when we target a more moderate blood glucose as well. They suggested that ICUs should develop protocols in collaboration with nursing and medical staff, which are locally applicable. These systematic algorithms should suggest adaptation of the rate of insulin using a dynamic rather than a sliding scale (e.g., adapting rate of infusion to nutritional support), the time for next glucose check, types of devices to be used for sampling, and sites of sampling. Once a protocol has been developed, all ICU healthcare providers should be educated on it. On implementation, the quality of this protocol can be evaluated by the incidence of hypoglycemia divided by the frequency of blood glucose checks, proportion of time in the target range, and blood glucose variability.⁴¹ By implementing such robust algorithms and protocols, we can strive to achieve better glycemic control in critically ill patients and at the same time reduce glucose variability and the occurrence of hypoglycemia.

These issues led to the consensus recommendations on measurement of blood glucose and reporting glycemic control in critically ill adults.³¹

Excerpts from the Consensus Recommendations on Measurement of Blood Glucose and Reporting Glycemic Control in Critically Ill Patients

- All patients whose severity of illness warrants an invasive vascular monitor should have blood glucose samples drawn from an arterial

line. If not available, as a second option, samples can be drawn from a central line. Only when severity of illness does not warrant an invasive line should capillary blood be used for sampling.

- Samples taken from arterial or central lines should be analyzed either in the central lab or using a blood gas analyzer. If delay with the central lab is unacceptable, blood gas analyzers should be the default analyzer. A glucometer is acceptable only when a capillary sample is taken from a patient considered to be too well to need invasive vascular access.

ADA Recommendations for Management of Blood Glucose in Critically Ill Patients

The American Diabetes Association in 2016 issued recommendations for the management of blood glucose in a critically ill adult based on the evidence available thus far⁴⁰:

- Continuous intravenous insulin infusion has been shown to be the best method for achieving glycemic targets in the critical care setting.
- Insulin therapy should be initiated for persistent hyperglycemia starting at a threshold greater than 180 mg/dL (10 mmol/L). Once insulin therapy is started, a target glucose range of 140–180 mg/dL (7.8–10.0 mmol/L) is recommended for the majority of critically ill and noncritically ill patients.
- More stringent goals such as 110–140 mg/dL (6.1–7.8 mmol/L) may be appropriate for selected critically ill patients, as long as this can be achieved without significant hypoglycemia.
- Intravenous insulin should be administered based on validated written or computerized protocols that allow for predefined adjustments in the infusion rate, accounting for glycemic fluctuations and insulin dose.
- A hypoglycemia management protocol should be adopted and implemented by each hospital. A plan for preventing and treating hypoglycemia should be established for every patient. Episodes of hypoglycemia in the hospital should be documented and tracked.
- The treatment regimen should be reviewed and changed if necessary to prevent further hypoglycemia when the blood glucose value is less than 70 mg/dL (3.9 mmol/L).

THE FUTURE

Recently, several investigators have substantiated the existence of three domains that clinicians need to consider when attempting to achieve a glycemic target: treatment of hyperglycemia, prevention of hypoglycemia, and the reduction of glycemic variability.^{6,9,10,21} Each one of these factors weighs in on improving outcomes in these patients. As clinicians, it is of paramount importance that we tailor insulin protocols based on the clinical picture of the patient to achieve an appropriate target glycemic control. Further research should be directed toward developing such protocols. The process may be labor intensive, but this, coupled with a standardized method for glucose measurement in the ICU, could provide us with data for further clinical research on the impact of glycemic control on outcomes in critically ill patients.

KEY POINTS

1. An increase in the levels of catecholamines, growth hormone, exogenous and endogenous glucocorticoids, and glucagon, along with an increase in circulating cytokines and peripheral insulin resistance, may play an important role in the genesis of stress-induced hyperglycemia.
2. In an attempt to reduce adverse outcomes associated with hyperglycemia, the ADA/ACCE recommend treating any blood glucose >180 mg/dL (10 mmol/L) in the critically ill.
3. Continuous intravenous insulin infusion has been shown to be the best method for achieving glycemic targets in the critical care setting.
4. Once insulin therapy is started, a target glucose range of 140-180 mg/dL (7.8-10.0 mmol/L) is recommended for the majority of critically ill and noncritically ill patients.
5. One glycemic target may not suit all ICU patients. We should probably seek different glycemic targets (and more robust insulin protocols to achieve such targets) that vary based on the presence of a diagnosis of diabetes and a previous chronic glycemic state.
6. Adaptive insulin infusion algorithms are recommended for the critically ill patient to reduce hypoglycemia and glucose variability.
7. Although laboratory blood glucose measurement is the gold standard, it is labor intensive and not practical for hourly measurements. Blood glucose measurement from arterial whole blood samples via an arterial line (vs. capillary blood), preferably using a blood gas analyzer (BGA) or a POCT, has been used successfully.

Anemia is a common clinical problem in critically ill patients. A large proportion of these patients are anemic on admission, and the majority of the remainder becomes anemic during their intensive care unit (ICU) stay. The likelihood of becoming anemic increases with the duration of stay in the ICU.

The traditional approach for the management of anemia in the ICU has been the administration of packed red blood cell (PRBC) transfusions. On average, about 40% of ICU patients are transfused (a mean of 5 units of PRBCs) in response to a mean pretransfusion hemoglobin (Hb) concentration of 8.5 g/dL.¹ Over the past decade, several studies have suggested that PRBC transfusion is independently associated with worse clinical outcomes, independent of the degree of anemia or the severity of illness. Myriad complications resulting from PRBC transfusion are increasingly being recognized, and the scarcity of blood (expected annual shortfall of 4 million units by 2030²) and economic impact of PRBC transfusion (approximately \$270 per unit transfused³ in the United States) have prompted a paradigm change for managing anemia in the ICU.

Current approaches include recognition of absolute indications for PRBC transfusion, avoidance of transfusions based on “transfusion triggers” alone, prevention of anemia in critically ill patients, use of PRBCs that have been stored in blood banks for shorter periods, and increasing acceptance of anemia. Many of these changes in approach are now evidence-based.

Future directions focus on the prevention of anemia, conservation of blood, and evaluation of blood substitutes.

EPIDEMIOLOGY

Anemia is defined as an Hb level less than 13 g/dL for adult males and less than 12 g/dL for adult nonpregnant females.⁴ Using this definition, more than 60% of all patients are anemic at admission, and the majority of those with normal Hb levels at admission become anemic while in the ICU.^{5,6} Given enough time, virtually all patients will become anemic during their ICU stay. In the anemia and blood transfusion in critically ill patients study (the ABC trial), 63% of patients had Hb levels below 12 g/dL, and 29% had Hb levels below 10 g/dL.⁵ Similarly, in the Transfusion Requirements in Critical Care (CRIT) study, the mean Hb level at baseline was 11 g/dL.⁶

The most frequent strategy for treatment of anemia is the transfusion of PRBCs. As a consequence, more than 14 million units are transfused annually in the United States.⁷ In patients with malignancy at their admission, the prevalence and incidence of anemia are 68% and 47%, respectively.⁸ Each day spent in the ICU increases the chance of being transfused by about 7%.⁹

ETIOLOGY

The etiology of anemia in the ICU is most often multifactorial, belonging to one or more of three major classes:

1. Hypoproliferative anemia due to bone marrow production defects
2. Ineffective erythropoiesis due to red cell maturation defects
3. Decreased survival of red cells secondary to blood loss, hemolysis, or both (Fig. 20-1)

The most common causes of anemia include phlebotomy for diagnostic laboratory testing, acute hemorrhage due to trauma,

gastrointestinal (GI) bleeding, or surgery—often exacerbated by the presence of coagulation abnormalities, treatment with chemotherapeutic agents, underlying chronic diseases such as renal and hepatic failure, reduced erythropoiesis, and shortened red cell survival.

Blood loss due to phlebotomy is an often unrecognized, yet significant, cause of anemia in the ICU, where patients are phlebotomized 4.6 times a day on average, with removal of 40 to 60 mL of blood daily.^{5,6,10,11} The volume of blood removed varies with the test being ordered, but average volumes typically drawn are presented in Table 20-1. The presence of an arterial line further increases the phlebotomized blood volume.¹¹ Approximately half of all patients are transfused as a direct result of phlebotomy.¹¹

Although rare since the advent of effective GI prophylaxis, GI bleeding can be a serious problem in the ICU. The overwhelming majority of critically ill patients demonstrates evidence of mucosal damage within the first 24 hours of admission. Overt anemia occurs in 5% of patients with stress-related GI bleeding, and clinically important bleeding necessitating transfusion is observed in 1% to 4% of critically ill patients.¹² Bleeding secondary to erosive gastritis is predominantly seen in patients on mechanical ventilation, those with coagulopathy, those with head injury, and/or those receiving corticosteroids.¹³

Reduced erythropoietin production is a key feature of anemia of critical illness, a distinct clinical entity similar to anemia of chronic disease. This blunted erythropoietic response to low Hb concentration in the face of apparently adequate iron stores is due to a failure to produce appropriate levels of erythropoietin.^{14,15} Blunted erythropoietin production in critically ill patients is probably mediated by proinflammatory cytokines such as tumor necrosis factor, interleukin (IL)-1, and IL-6, which downregulate expression of the gene encoding erythropoietin.¹⁶ IL-6 inhibits renal erythropoietin production.¹⁷ Additional contributory effects of these proinflammatory cytokines include induction of a state of relative iron deficiency, vitamin deficiency, and altered iron metabolism in the bone marrow.^{6,18} Therefore, anemia is a result of both a blunted response to erythropoietin and abnormalities in iron metabolism.

LABORATORY EVALUATION OF ANEMIA IN THE INTENSIVE CARE UNIT

A comprehensive treatise on the evaluation of anemia is beyond the scope of this chapter. Discussion here is limited to pertinent iron studies that aid in the diagnosis of anemia of critical illness. A brief review of iron metabolism is essential to understanding the rationale behind the laboratory tests ordered.

Iron absorbed from food or released from stores circulates in plasma as bound to transferrin, the iron transport protein. This iron-transferrin complex interacts with a specific transferrin receptor protein on the surface of early erythroid cells. This complex is then internalized and the iron released intracellularly. Within the erythroid cells, iron in excess of that needed for Hb synthesis binds to the storage protein apoferritin, forming ferritin. Iron in the ferritin pool can be released and reused in the iron metabolism pathway. The levels of ferritin in serum correlate with total body iron stores and are therefore a suitable laboratory estimate of iron stores.¹⁹ During maturation of reticulocytes to erythrocytes, the cells lose all activities of the Hb-synthesizing system, including surface expression of the

| Standard discard amount | 2 mL |

transferrin receptors, which are released into circulation.²⁰ Levels of transferrin receptor protein in circulation provide a quantitative measure of total erythropoiesis and can be used to measure the expansion of the erythroid marrow in response to recombinant erythropoietin therapy. Serum iron levels represent the amount of circulating iron bound to transferrin. The total iron-binding capacity is an indirect measure of the circulating transferrin concentration.

Key tests necessary for establishing a complete diagnosis of anemia of critical illness include serum iron concentration, serum transferrin concentration, transferrin receptor protein concentration, total iron-binding capacity, and serum ferritin concentration.

Anemia of critical illness is caused by impaired iron release, reduced production of erythropoietin, and a blunted response to erythropoietin; thus, this syndrome is characterized by a low serum iron concentra-

tion, low total iron-binding capacity, low transferrin saturation, normal transferrin-receptor protein levels, and a normal to high ferritin level. In contrast, iron-deficiency states are associated with transferrin saturation less than 18%. Consequently, critically ill patients may develop iron-deficiency anemia, anemia of chronic disease, or a combination of both.

MANAGEMENT

Red Cell Transfusion

Transfusion of PRBCs remains the standard approach for the management of anemia in critically ill patients. Most transfusions are administered in response to a particular Hb level, known as the *transfusion trigger*. Historically, transfusion was indicated for Hb concentrations below 10 g/dL. However, several considerations led to the critical reevaluation of this approach. First, scientific evidence suggests that most critically ill patients safely tolerate lower Hb levels. Second, PRBC transfusions are associated with numerous potential complications. Third, blood is a scarce and costly resource that may not always be available²¹; hence, its use must be limited to those most likely to benefit. Transfusion of PRBCs must therefore be used for a physiologic indication and not only in response to a transfusion trigger.

In recent years, evidence has led us to reconsider the traditional liberal strategy of transfusion. In the ABC trial, a prospective observational study of 3534 patients from 146 western European ICUs, 37% of all patients were transfused while in the ICU. A majority of transfusions were performed during the first week of ICU stay.

Transfusion was more common in the elderly and in those with ICU stays longer than 1 week. Notably, mortality was significantly higher in the transfused than in the nontransfused group. The differences persisted even after the patients were matched for the degree of organ dysfunction.⁵ The CRIT study was a prospective, multicenter, observational study of 284 ICUs in 213 hospitals in the United States. Overall, 44% of patients were transfused, most often within the first week of ICU admission; transfusion was independently associated with longer ICU and hospital stays and increased mortality.⁶ Walsh and colleagues prospectively collected data on 1023 sequential admissions in 10 ICUs over 100 days in Scotland. Approximately 40% of patients were transfused, even with the application of evidence-based transfusion guidelines.²² The multicenter trials group of the American Burn Association studied patients with more than or equal to 20% total body surface burns at 21 burn centers in the United States and Canada. Overall, they found that nearly 75% of patients were transfused during their hospital stay, receiving a mean of 14 units. The number of units transfused correlated significantly with the number of infections and mortality.²³ In a prospective observational study by the North Thames Blood Interest Group, 53% of patients were transfused for a mean pretransfusion Hb level of 8.5 g/dL. About two-thirds were transfused for low Hb levels and only 25% for hemorrhage. ICU mortality in the transfused patients was significantly higher than that in the nontransfused patients (24.8% vs. 17.7%, respectively).²⁴

Anemia is not as poorly tolerated in critically ill patients as previously thought. Some clinical evidence comes from studies in Jehovah's Witness patients who refuse to accept PRBC transfusions on religious grounds. Mortality increases significantly at Hb values below 5 g/dL, more so in individuals older than 50 years.²⁵ In conscious healthy volunteers, isovolemic dilution can be tolerated until the Hb concentration decreases to 5 g/dL, without an increase in lactate concentration²⁶; however, significant cognitive changes were noted.²⁷

The risks of anemia must be balanced against the potentially deleterious effects of transfusion, especially since the efficacy of PRBC transfusions to augment oxygen delivery and the impact of this increase on tissue metabolism and clinical outcome remain unproven. Marik and Corwin analyzed outcomes in 272,596 patients as reported in 45 studies. Blood transfusion was associated with an increased risk of death, infectious complications, and development of acute respiratory distress syndrome (ARDS).²⁸

The only absolute indication for PRBC transfusion is in the therapy of hemorrhagic shock.²⁹ However, only 20% of transfusions are used for this indication.

Most transfusions in the ICU are performed for the treatment of anemia. In the CRIT trial, over 90% of transfusions were given for this reason.⁶ Perceived benefits of transfusion include increase in oxygen delivery to the tissues, increase in cell mass and blood volume, alleviation of symptoms of anemia including dyspnea, fatigue, and diminished exercise tolerance, and relief of cardiac effects. The optimal Hb concentration can be influenced by the premorbid health status, disease process, and other factors. The seminal Transfusion Requirements in Critical Care (TRICC) trial has been instrumental in changing transfusion practices over the past decade.³⁰ In this study, 838 euvoletic critically ill patients with Hb levels less than 9 g/dL were enrolled. Among these, 418 patients were randomly assigned to a restrictive transfusion strategy, where transfusion was provided if the Hb level fell below 7 g/dL, with a goal of maintaining circulating Hb concentration between 7 and 9 g/dL; the remaining 420 patients were assigned to the liberal transfusion group and received transfusions if the Hb levels were less than 10 g/dL, with transfusions provided to keep the Hb level between 10 and 12 g/dL. Overall the 30-day mortality was similar between the two groups (18.7% vs. 23.3%, $P = 0.11$). However, a significantly lower mortality was seen with a restrictive transfusion strategy in those less severely ill who had APACHE II scores of less than or equal to 20 (8.7% vs. 16.1%, $P = 0.03$) and in those younger than 55 years (5.7% vs. 13.0%, $P = 0.02$). No difference in mortality was observed in those with stable, clinically significant cardiac disease (20.5% vs. 22.9%, $P = 0.69$). This strategy resulted in a 54% decrease in the average number of units

transfused and avoidance of transfusion in 33% of patients. Lowering of the transfusion threshold, therefore, is a simple and inexpensive strategy for improving the outcome for critically ill patients. Caution must be used in applying this restrictive transfusion strategy to those patients with acute myocardial ischemia and unstable angina as this group was excluded from the TRICC trial. Compensatory cardiac mechanisms in anemic patients include increases in blood flow during rest and redistribution of blood away from the endocardium. In the presence of significant coronary artery disease, these adaptive changes are poorly tolerated, and anemic patients with myocardial infarction may have increased mortality.³¹

ADVERSE EFFECTS OF TRANSFUSION

A large proportion of ICU patients continue to receive PRBC transfusions for anemia, exposing them to serious risks, including transmission of infectious diseases, immune-mediated reactions (acute or delayed hemolytic reactions, febrile allergic reactions, anaphylaxis, and graft-versus-host disease), and non-immune-related complications (fluid overload, electrolyte toxicity, and iron overload). Transfusion-related complications are encountered in up to 4% of PRBC transfusions.⁶ The risk of adverse outcomes increases incrementally with each unit of PRBC transfused.^{32,33} In an observational cohort study of 5814 patients undergoing coronary artery bypass grafting, each unit of PRBC transfused resulted in more complications. Overall, there was a 73% increase in the odds of a major morbidity for each unit transfused (Table 20-2).³²

With advances in screening and improvements in blood banking technology, transmission of infectious agents is less common. Current estimates of the risk of infection per unit of blood are approximately 1 in 2 million for human immunodeficiency virus, 1 in 1 million for hepatitis C virus, and 1 in 100,000 for hepatitis B virus.³⁴ The most common transfusion-related infections are secondary to bacterial contamination, which has an incidence of 12.6 events per 1 million

TABLE 20-2

Potential Adverse Consequences Associated with Red Cell Transfusion⁸⁸

INFECTIOUS COMPLICATIONS

| | |
|---|---------------------------------|
| Human immunodeficiency virus infection | 1 in 2.3 million |
| Human T-lymphotropic virus infection | 1 in 2 million |
| Hepatitis C virus infection | 1 in 1.8 million |
| Hepatitis B virus infection | 1 in 350,000 |
| Parvovirus B19 virus infection | 1 in 10,000 |
| Bacterial infections (<i>Staphylococcus</i> , streptococci, <i>Yersinia enterocolitica</i> , etc.) | 1 in 250,000 |
| Parasitic infections (Chagas disease) | 1 in 29,000 donors seropositive |

NONINFECTIOUS COMPLICATIONS

| | |
|--|--|
| Hemolytic transfusion reactions | 1 in 10,000 to 1 in 50,000 |
| Delayed hemolytic transfusion reaction | 1 in 1500 |
| Febrile nonhemolytic transfusion reactions | 1 in 100 to 35 in 100 |
| Major allergic reactions | 1 in 20,000 to 1 in 50,000 |
| ABO mismatching | 1 in 14,000 to 1 in 38,000 |
| Transfusion-related acute lung injury (TRALI) | 1 in 5000 |
| Transfusion-related immunomodulation (TRIM) | 1 in 100 |
| Transfusion-associated circulatory overload (TACO) | Observed once two blood volumes replaced |
| Coagulopathy | Observed after transfusion of 10 to 15 units |
| Iron overload | |
| Hypothermia | |
| Hyperkalemia | |
| Thrombocytopenia | |
| Pulmonary hypertension | |

units of allogeneic blood components transfused.³⁵ The risk of bacterial contamination is higher for PRBCs than for whole blood. Transfusion-related bacterial infections are most often caused by gram-positive organisms (e.g., staphylococcal spp., streptococcal spp., 58%) but may also be caused by gram-negative organisms (e.g., *Yersinia enterocolitica*, 32%). About 10% of these infections will result in a fatal outcome.³⁵ Increasing global travel has led to the emergence of infectious diseases not usually seen in the United States. Chagas disease, caused by the parasitic protozoan *Trypanosoma cruzi*, is endemic in much of South and Central America. Immigrants from these endemic areas now form an increasing proportion of the blood donor pool. This issue is especially relevant in regions with high immigrant populations. In two such cities, Los Angeles and Miami, seropositive rates among donors were one in 7500 and one in 9000, respectively, and have been increasing.³⁶ Once acquired, the parasitemia persists long after acquisition of the infection.³⁷

Major ABO blood type mismatching is estimated to occur in 1 of 138,673 PRBC units transfused and results in 1 death per 2 million units transfused.³⁵ Incompatibility may also result from antigens not routinely detected by current antibody assays. As a consequence, fatal acute hemolytic reactions still occur in 1 of every 250,000 to 1 million transfusions, and 1 patient per 1000 demonstrates the clinical manifestations of a delayed hemolytic transfusion reaction.³⁸

Transfusion-related acute lung injury (TRALI) is a potentially serious pulmonary complication of transfusion. In severe cases, its clinical presentation is similar to that of ARDS.³⁹ Although initially described by Bernard in 1951⁴⁰ as noncardiogenic pulmonary edema related to transfusion, the term *TRALI* was coined by Papovsky et al.⁴¹ Transfusion-related acute lung injury (TRALI) presents with dyspnea and bilateral pulmonary edema during or within up to 6 hours of a transfusion, with no other risk factor to explain its development. It must be distinguished from pulmonary insufficiency due to circulatory overload. Hypoxemia, fever, hypotension, tachycardia, and cyanosis may also occur. Most often, symptoms appear within 1 or 2 hours following transfusion, but a delayed form with dyspnea appearing as late as 48 hours after transfusion has been reported. Chest X-ray shows bilateral infiltrates, which may progress and cause whiteout of the entire lung field. Differential diagnosis includes transfusion-associated circulatory overload, cardiac diseases, allergic and anaphylactic transfusion reactions, and bacterial contamination of the blood. Although the exact incidence is unknown, TRALI is estimated to occur in one of every 5000 transfusions.⁴² Current evidence suggests two forms of TRALI: immune and nonimmune. Potential mediators include antileukocytic antibodies, lipid peroxidation products, and other as yet unrecognized agents. Neutrophils are the key effector cells. Transfusions from multiparous female donors, owing to exposure to paternal leukocytes, are associated with the highest risk of the development of TRALI in the recipient.⁴³ Treatment is currently limited to supportive measures.

Transfusion-related immunomodulation (TRIM) results in an increased incidence of bacterial infections, cancer recurrence, and organ dysfunction.^{44,45} Opelz and colleagues first suggested clinical evidence of transfusion-associated immunomodulation in 1973, when improved renal allograft survival was observed in patients transfused prior to transplantation.⁴⁶ Current evidence implicates transfusions in the development of nosocomial infections including wound infections, pneumonia, and sepsis. In a prospective observational study, Taylor et al. found a significant association between transfusion and development of nosocomial infections (14.3% vs. 5.3%, $P < 0.0001$). In addition, mortality and length of stay were increased in the transfused group. The risk of infection increases 9.7% for each unit of PRBC transfused.⁴⁷ Development of these infectious complications results not only in increased length of stay but in increased in-hospital deaths and increased costs as well.⁴⁸ These effects may be reduced by the use of prestorage leukocyte depletion.⁴⁹ Other complications include transfusion-associated circulatory overload (TACO) with the development of fluid overload and pulmonary edema^{50,51} and pulmonary hypertension with a decreased right ventricular ejection fraction.⁵² Finally, the transfusion of PRBCs may not augment the oxygen-

carrying capacity of blood. This results from development of the "storage lesion" due to changes in red blood cells that occur during ex vivo storage. These changes are both structural and functional^{53,54} and include reduced deformability impeding microvascular flow,⁵⁵ altered adhesiveness and aggregation,⁵⁶ reduced intracellular levels of 2,3-diphosphoglycerate (which shifts the oxyhemoglobin dissociation curve to the left and reduces oxygen delivery to the tissues), reduced levels of nitric oxide and adenosine triphosphate,⁵⁷ and accumulated bioactive compounds with proinflammatory activity.⁵⁸ The risk of complications increases with the duration of storage.^{59,60} Koch and colleagues examined data from 6002 patients undergoing cardiac surgery. Patients given older blood had higher rates of in-hospital mortality and more complications.⁶¹ Other recent studies have not found such an effect of storage.

Role of Erythropoietin

Many factors contribute to the development of anemia in critically ill patients, but inappropriately low endogenous levels of erythropoietin in response to anemia represent a key pathophysiologic issue. Further, there is a failure of circulating erythropoietin to induce a response commensurate with the degree of anemia.⁶² Recognition of these considerations has prompted the use of pharmacologic doses of erythropoietin in an effort to reduce the need for and/or the amount of red cells transfused, but this approach has not been validated by scientific evidence. Corwin et al. conducted a prospective randomized, placebo-controlled trial (EPO3) on 1460 patients and found that epoetin alfa therapy did not decrease the number of PRBC units transfused and did not improve outcomes. Furthermore, a significant increase in thrombotic events was noted (hazard ratio, 1.41; 95% CI, 1.06-1.86).⁶³ Accordingly, routine use of erythropoietin cannot be recommended. At our institutions, erythropoietin use is limited to patients with chronic renal failure and Jehovah's Witnesses.

Current Recommendations

Transfusion of PRBCs should not be based on a transfusion trigger alone. The decision must be based instead on the patient's intravascular volume status, evidence of shock, duration and extent of anemia, and cardiopulmonary physiologic parameters.¹

Transfusion is indicated for patients with hemorrhagic shock. In this instance, the number of units transfused is based not on a particular Hb level but rather on the physiologic state of the patient. Transfusion is also indicated in the presence of evidence of acute hemorrhage with either hemodynamic instability or evidence of inadequate oxygen delivery as demonstrated by elevated blood lactate levels or base deficit. Serial assessment of these parameters can be used to determine the efficacy of resuscitation.⁶⁴

In hemodynamically stable patients with anemia, a restrictive strategy of transfusion can be employed. Transfusion with PRBCs should be instituted when the Hb level falls to less than 7 g/dL. For patients at risk of myocardial ischemia, a higher Hb concentration might be the appropriate transfusion trigger.

For patients with cardiac disease undergoing coronary artery bypass graft surgery, increased mortality is observed in patients with Hb levels below 8 g/dL on admission. Reduction in mortality can be achieved by transfusing to a hematocrit of 30% to 33%. No mortality benefit is seen with hematocrits above 33%, and increased mortality is observed when hematocrits above 36% are achieved.⁶⁵⁻⁶⁷

Use of transfusions to wean patients from mechanical ventilation is not indicated. No benefit in the weaning process or difference in duration of mechanical ventilation has been observed.⁶⁸

Transfusions should not be employed as the absolute method to improve tissue oxygen delivery in critically ill patients. In septic patients, PRBC transfusion increases oxygen delivery but not consumption.⁶⁹ Although increases in Hb levels are consistently seen following transfusion in septic patients, these increases do not necessarily translate to improvement in tissue oxygenation.⁷⁰ Transfusion may be

BOX 20-1**Summary of Current Recommendations¹**

1. Packed red blood cell (PRBC) transfusion is indicated in patients with hemorrhagic shock (level 1).⁸⁹
2. PRBC transfusion may be recommended for patients with acute hemorrhage after adequate fluid resuscitation if they have evidence of hemodynamic instability or evidence of inadequate systemic perfusion as demonstrated by elevated serum lactate or presence of a base deficit (level 1).⁶⁴
3. A restrictive strategy of transfusion for hemoglobin (Hb) levels <7 g/dL is recommended for hemodynamically stable critically ill patients, except for those with myocardial infarction or unstable angina.⁹⁰ This restrictive strategy is also recommended in critically ill trauma patients⁹¹ and in those with stable cardiac disease (level 1).⁹⁰
4. Transfuse patients with acute coronary syndromes who have admission Hb levels of <8 g/dL. Achieve posttransfusion hematocrit (Hct) of 30% to 33% (level 3).^{66,67,92}
5. Do not transfuse based on a transfusion trigger alone. Instead, individualize the decision based on the patient's intravascular volume status, evidence of shock, duration and extent of anemia, and cardiopulmonary status.
6. Transfuse as single units (level 5).¹
7. Do not use transfusion as a means to wean patients off mechanical ventilation (level 2).⁵
8. Do not use transfusion as a stand-alone strategy to improve tissue oxygen delivery (level 2).³³
9. In sepsis, transfusions can be recommended as part of a strategy of early goal-directed therapy during the initial resuscitation⁹⁴ (level 2).⁷⁰
10. Evidence for transfusion in patients with subarachnoid hemorrhage and traumatic brain injury should be individualized.^{95,96}

indicated for failure to achieve an adequate mixed venous saturation after adequate fluid resuscitation.⁷¹

TRICC data fail to show any difference in outcome with a restrictive strategy in patients with traumatic brain injury, but the study was underpowered to detect differences in this subgroup of patients.⁷² Others have shown transfusion-related improvement in brain tissue partial pressure of oxygen independent of cerebral perfusion pressure, arterial oxygen saturation, and fraction of inspired oxygen (FiO₂).⁷³ Similar improvements have been observed in patients with subarachnoid hemorrhage who had higher initial and mean Hb values.⁷⁴ Salim et al. retrospectively evaluated the effect of transfusion on outcomes in 1150 patients with traumatic brain injury. On logistic regression, when both anemia and transfusion were included in the model, transfusion resulted in an increased mortality while anemia did not. When transfusion was removed from the model, anemia was a significant risk factor for mortality and complications.⁷⁵ These confounding results preclude a definitive recommendation for patients with subarachnoid hemorrhage or brain trauma, and the decision to transfuse must be individualized. Recommendations are summarized in [Box 20-1](#).

Novel Strategies

It is evident that hemodynamically stable patients can tolerate marked degrees of anemia. Inasmuch as the transfusion of PRBCs is clearly deleterious, preventing the development and/or progression of anemia is of paramount importance. Strategies to achieve this include retrieving and reusing blood shed during surgery,⁷⁶ limiting transfusions, using low-volume adult or pediatric sampling tubes to reduce phlebotomy volumes, reducing the number of laboratory tests ordered, using point-of-care microanalysis for laboratory tests, and using closed blood conservation devices.⁷⁷

Other approaches may include the development of newer methods of blood storage,⁷⁸ use of advanced computing technologies to optimize the use of blood inventories,⁷⁹ and development of blood substitutes.

Blood substitutes are being developed largely in response to concerns regarding the potential transmission of infectious agents and the impending shortage of blood in the face of increasing demands.⁸⁰ Blood substitutes offer the distinct advantages of better shelf life

compared to banked blood, universal compatibility, clinically useful intravascular half-life (18-24 hours), and freedom from the risk of infectious disease transmission (possibly with the exception of prion-mediated diseases). Blood substitutes are also oncologically active and can increase blood volume by an amount in excess of the transfused volume.⁸¹ Furthermore, blood substitutes can improve microcirculatory flow by reducing blood viscosity.⁸² Most Hb-based oxygen carriers (HBOCs) scavenge nitric oxide and promote arteriolar vasoconstriction on this basis. Although nitric oxide scavenging was probably the cause of increased mortality in the trial of diaspirin cross-linked hemoglobin (DCLHb) for trauma victims,⁸³ nitric oxide scavenging might prove beneficial in septic patients. In septic patients, inducible nitric oxide synthase expression is increased, leading to overproduction of nitric oxide and hypotension on this basis. HBOCs might overcome this distributive shock and restore blood pressure,⁸⁴ but their use has also been disappointing.

McKenzie and colleagues recently described the outcome in 54 patients with severe life-threatening anemia (median Hb level, 4 g/dL) treated with the blood substitute HBOC-201; 23 (41.8%) of 54 patients survived to discharge. Survival was significantly more likely when the blood substitute was administered earlier (3.2 days in survivors vs. 4.4 days in nonsurvivors, $P = 0.027$).⁸⁵

Results were from small individual studies, and available data do not support the use of blood substitutes in their current form. In a meta-analysis of 16 trials involving five blood substitutes and over 3700 patients, Natanson and colleagues⁸⁶ found a significantly increased risk of myocardial infarction and death among HBOC-treated patients. Poorer outcome was not related to the type of blood substitute employed or the clinical indication for its use. In light of this evidence, future phase 3 trials of these products are not warranted.

KEY POINTS

1. Anemia is exceedingly common in patients admitted to the ICU. Over 60% are anemic on admission, and more than 80% become anemic by day 3 of their ICU stay.
2. Anemia in the critically ill patient is multifactorial in etiology. Iron-deficiency anemia and anemia of critical illness are the most frequent causes.
3. Anemia of critical illness is cytokine-mediated and results from decreased production of erythropoietin, reduced response to erythropoietin, and altered iron metabolism.
4. Transfusion is clearly indicated for hemorrhagic shock and hemodynamic instability associated with blood loss after adequate fluid resuscitation.
5. Transfusion of packed red blood cells is still employed by the majority of clinicians as the mainstay of therapy for anemia in critical illness. However, the optimal Hb concentration essential to maintain ideal tissue oxygen delivery remains unknown.
6. A restrictive transfusion strategy for critically ill, hemodynamically stable patients without evidence of cardiac ischemia. Transfusion in these patients can often be avoided when circulating Hb level is above 7 g/dL.
7. Treatment with recombinant human erythropoietin initially showed promise as a strategy for reducing exposure to allogeneic blood. More recent evidence, however, refutes these findings and points instead to an increase in thrombotic complications.
8. Novel strategies to avoid the need for blood transfusion include use of blood conservation techniques, improved blood storage techniques, advanced inventory control, and evaluation of the efficacy of blood substitutes.

Thrombocytopenia is a common laboratory finding in critically ill patients. Up to 50% of patients develop platelet counts $<150 \times 10^9/L$, and severe thrombocytopenia ($<50 \times 10^9/L$) occurs in at least 5% to 20%.¹⁻³ Pronounced thrombocytopenia is associated with an increased bleeding risk⁴ but can also be the result of immune-mediated platelet activation that provokes a prothrombotic state. The treatment of thrombocytopenia differs depending upon the underlying causes.

PLATELET PHYSIOLOGY AND REGULATION OF PLATELET COUNT

Platelets are nucleus-free fragments of megakaryocytes. Their production is controlled by thrombopoietin (TPO), a growth factor that is primarily produced in the liver in a constant amount.⁵ Only circulating “free” TPO stimulates platelet production. TPO binds to specific receptors on circulating platelets and is thereby removed from the circulation. Therefore, higher platelet counts decrease free TPO levels and platelet production, while low platelet numbers result in higher plasma levels of free TPO and consequently enhanced platelet production.⁶ The two compartments of platelets are as follows: (1) the stationary compartment in the spleen, comprising about one-third of the whole platelet pool, and (2) circulating platelets, representing the remaining two-thirds. The two pools exchange freely. After a mean life span of about 10 days, platelets are eliminated by the reticuloendothelial system of the liver and spleen.

The platelet count is controlled by complex interactions between production, pooling, and elimination.^{6,7} Nevertheless, in healthy people, the platelet count usually remains quite constant.⁸ Thus, thrombocytopenia is a marker for an alteration of normal physiology. In intensive care unit (ICU) patients, thrombocytopenia is associated with increased mortality,⁹ **not because of increased bleeding but as a marker for severe morbidity.**

ETIOLOGY OF THROMBOCYTOPENIA

Thrombocytopenia occurs when platelet loss and/or consumption exceeds production. The following six underlying mechanisms can be distinguished, although more than one often contributes to thrombocytopenia in an individual patient: (1) pseudothrombocytopenia, (2) hemodilution following platelet loss as a result of bleeding, (3) platelet consumption (e.g., due to sepsis, bleeding, or extracorporeal circuits), (4) decreased platelet production (e.g., due to toxic bone marrow depression), (5) increased sequestration of platelets (e.g., due to hepatomegaly and/or splenomegaly), and (6) immune-mediated destruction of platelets.¹⁰ **Table 21-1** summarizes the most frequent differential diagnoses of thrombocytopenia in the ICU, their frequency, and some diagnostic clues.

DIAGNOSTIC APPROACH TO THROMBOCYTOPENIA

Confirmation of Thrombocytopenia

The first question when facing a patient with thrombocytopenia should be whether the low platelet count is actually pseudothrombocytopenia, an artifact caused by in vitro aggregation of platelets in the blood sample due to naturally occurring immunoglobulin M antibodies

directed against epitopes on platelet glycoprotein (GP) IIb/IIIa-receptors, which are expressed upon calcium chelation by ethylene diaminetetraacetic acid (EDTA).^{11,12} The diagnosis is made by repeating the platelet count measurement using a citrated blood sample and/or examining the blood smear for the presence of platelet aggregates. *Note:* During treatment with GPIIb/IIIa antagonists, pseudothrombocytopenia can occur in citrated blood.

Identification of the Underlying Cause of Thrombocytopenia

Clinical Context

Sepsis, disseminated intravascular coagulation (DIC), and nonimmune drug-induced thrombocytopenia (DTP) are the most common causes of thrombocytopenia in critically ill patients.¹³ Less frequent causes include thrombotic microangiopathies, heparin-induced thrombocytopenia (HIT), immune thrombocytopenia (ITP), drug-induced immune thrombocytopenias (DITP), and post-transfusion purpura (PTP). These special clinical conditions are discussed in more detail below.

History

A detailed history should include previous drugs (for DTP and DITP); dietary habits, including alcohol consumption; risk factors for HIV and infectious hepatitis; and previous transfusions (for PTP). Data regarding previous platelet count values is important for distinguishing between chronic or acutely acquired thrombocytopenia.

Physical Examination

Physical examination is necessary to quantify bleeding symptoms and to estimate the bleeding risk. New thrombosis manifesting shortly before or after the onset of thrombocytopenia should prompt suspicion for HIT, while hepatomegaly and palmar erythema suggest cirrhosis and its associated complex clotting disorder.

Laboratory Assessment

Initial laboratory tests comprise the following: a complete blood count to exclude other cytopenias; a differential blood smear to identify leukemia, nucleated red cells, or fragmented cells; measurements of prothrombin time, activated partial thromboplastin time (aPTT), and fibrinogen for the detection of DIC; liver function tests and liver enzymes for the diagnosis of hepatopathy; and the measurement of lactate dehydrogenase as a sign of possible hemolysis. Further specific laboratory tests should follow depending upon the results of these initial screening assays. For example, a test for platelet factor 4 (PF4)/heparin antibodies should be obtained when HIT is suspected.¹¹

Platelet Count Course

The platelet count course is typically biphasic in ICU patients. After an initial mild decrease reaching a platelet count nadir on days 2 to 4 after ICU admission, platelet counts increase to higher than prebaseline values, a phenomenon called reactive thrombocytosis (**Fig. 21-1**). Persistent thrombocytopenia after trauma/major surgery hints toward consumption, bleeding, or severe organ damage, while a slow decrease in the platelet count over several days is rather typical for infection or bone marrow toxicity. When the platelet count falls a second time within 2 to 3 days during the second week of treatment,

TABLE 21-1

Major Mechanisms of Thrombocytopenia, Typical Clinical Scenarios, and Relative Frequencies in the Intensive Care Unit

| MECHANISM AND DIFFERENTIAL DIAGNOSIS | CLINICAL SCENARIO/DIAGNOSTIC APPROACH | FREQUENCY IN THE CRITICALLY ILL |
|--|---|---------------------------------|
| PSEUDOTHROMBOCYTOPENIA | | |
| Platelet aggregates in EDTA-anticoagulated blood or therapy with GPIIb/IIIa-receptor antagonists | Unexpected thrombocytopenia in the absence of bleeding symptoms; therapy with GPIIb/IIIa-receptor antagonists. Repeat platelet count in citrated blood and control for aggregates in the blood smear. Note: GPIIb/IIIa antagonists often induce pseudothrombocytopenia in citrated blood also | <5% |
| HEMODILUTION | | |
| Infusion of fluids and/or plasma | Massive bleeding with consecutive massive infusion/transfusion | Common |
| PLATELET CONSUMPTION | | |
| Blood loss | Bleeding, anemia, and prolonged clotting times | Common |
| Massive blunt trauma | History and physical and radiologic examination | Common |
| Disseminated intravascular coagulation | Shock, infection or other typical underlying causes (see text), prolonged clotting times, and increased fibrin split products | Very common |
| Sepsis | Fever and further sepsis criteria, positive blood cultures | Very common |
| Extracorporeal circuit | Organ failure requiring extracorporeal circuit | Common |
| PLATELET SEQUESTRATION | | |
| Hepatosplenomegaly | History, sonography, or other diagnostic radiology | Common |
| DECREASED PLATELET PRODUCTION | | |
| Intoxication (alcohol and other drugs) | History of substance abuse or medication, typical laboratory findings for alcohol abuse | Common |
| Viral infection (HIV, HCV, EBV, CMV) | Diagnostic work-up of viral infections | Rare |
| Bone marrow infiltration (leukemia, tumors) | Bone marrow examination and nucleated red cells in the differential blood film | Rare |
| Radiation | History | Rare |
| Chemotherapy | History | Rare |
| PLATELET DESTRUCTION | | |
| Immune thrombocytopenia | Anti-platelet antibodies, normal or increased megakaryocytes in bone marrow, and normal or decreased thrombopoietin | Rare |
| Drug-induced immune thrombocytopenia | Medication history, platelet counts $< 10,000/\mu\text{L}$, specific antibodies, increase of platelet counts after cessation of suspected/laboratory confirmed drug | Rare |
| Heparin-induced thrombocytopenia | 50% decrease in platelet count (typical nadir $20\text{--}80,000/\mu\text{L}$) between day 5 and 14 of heparin treatment, w/o thromboembolic events with ongoing heparin therapy, platelet factor 4/heparin antibodies | 0.5-1% |
| Thrombotic microangiopathies (TTP, HUS, HELLP syndrome) | Hemolysis with negative direct Coombs test, fragmented red cells in blood smear, typical platelet count nadir $10\text{--}30 \times 10^9/\text{L}$, thrombotic events with neurologic (TTP) or renal (HUS) symptoms, pregnancy (HELLP syndrome) | Rare |
| Post-transfusion purpura | Transfusion history and history of pregnancy | Very rare |

FIGURE 21-1 ■ Daily platelet counts in intensive care unit (ICU) survivors (filled squares) and nonsurvivors (unfilled circles) during 10 days in the ICU. Data are obtained from a prospective observational study in surgical/medical intensive care patients.²⁵

immune-mediated causes, such as HIT or PTP, should be considered. With HIT, the platelet count typically decreases by $>50\%$, but the nadir is 30 to $80 \times 10^9/\text{L}$. With PTP or DITP, the nadir is typically $<10 \times 10^9/\text{L}$.¹⁴ As a rule of thumb, platelet count nadir values of $>20 \times 10^9/\text{L}$ are more typical for nonimmune disorders (other than HIT), while platelet counts of $<10 \times 10^9/\text{L}$ should raise suspicion for an underlying immune-mediated process.

PLATELET TRANSFUSION

As many ICU patients also have a concomitant platelet function disorder caused by medications or platelet preactivation on extracorporeal circuits, the clinical symptoms are much more relevant than the absolute platelet count to decide on the indication for platelet transfusions. Bleeding \geq WHO grade 2 (i.e., more than mild blood loss like in epistaxis, hematuria, and hematemesis¹⁵) is a well-established trigger for platelet transfusion.¹⁶ Retinal bleeding and/or spontaneous bleeding of the oropharyngeal mucous membranes (wet purpura) indicate an increased risk for life-threatening bleeding into the central nervous system (CNS).

Patients with immune-mediated thrombocytopenia should only receive platelet transfusions in cases of serious or life-threatening hemorrhage.

Prophylactic platelet transfusions are given to prevent spontaneous serious bleeding or bleeding in the context of invasive procedures. The AABB¹⁵ recommends the transfusion of a single therapeutic unit (1 apheresis unit or 4-6 pooled platelet concentrates) in hospitalized adult

TABLE 21-2 Recommended Triggers for Platelet Transfusion (Data From¹⁵)

| TRANSFUSION INDICATION | THRESHOLD PLATELET COUNT ($\times 10^9/L$) | STRENGTH OF RECOMMENDATION | QUALITY OF EVIDENCE |
|--|--|----------------------------|---------------------|
| Prophylactic transfusion of adult patients | 10 | Strong | Moderate |
| Before central vein catheter placement | 20 | Weak | Low |
| Before elective diagnostic lumbar puncture | 50 | Weak | Very low |
| Before major elective surgery (excluding neurosurgery) | 50 | Weak | Very low |
| Prophylactic transfusion of nonthrombocytopenic patients before cardiopulmonary bypass surgery | No transfusion (only in case of bleeding) | Weak | Very low |
| Patients with intracranial hemorrhage and antiplatelet drugs | Independent of the platelet count | Uncertain | Very low |

patients with a platelet count of $\leq 10 \times 10^9/L$ to reduce the risk for spontaneous bleeding. A higher threshold of 20 to $30 \times 10^9/L$ should be considered in febrile and septic patients¹⁷ and even higher in patients with concomitant platelet dysfunction. These recommendations are supported by several randomized controlled trials in hematologic patients with radiation and/or chemotherapy-induced hypoproliferative thrombocytopenia; however, no data exist for ICU patients. It might be reasonable to restrict platelet transfusions to ICU patients with symptomatic bleeding, also because no study demonstrates that ICU patients benefit from platelet transfusions with regard to bleeding or mortality.¹⁸ The recommendations for platelet transfusion before invasive procedures¹⁵ (Table 21-2) are supported by observational studies. No data exist for patients at risk for bleeding in the CNS or those undergoing neurosurgery. For these patients, a transfusion threshold of $100 \times 10^9/L$ is often recommended.

Transfusion of a single therapeutic platelet unit should increase the platelet count by $\approx 15 \times 10^9/L$ in an ICU patient.¹⁸ Otherwise, persistence of the underlying cause of thrombocytopenia and/or immune-mediated etiologies must be considered.

THROMBOCYTOPENIA IN SPECIAL CLINICAL SCENARIOS

Sepsis

With a relative incidence of approximately 50%,^{9,19,20} sepsis is the most common reason for thrombocytopenia in ICU patients as a result of decreased platelet production and increased platelet consumption and destruction. Despite increased TPO levels in septic patients, platelet production is decreased, probably due to the active phagocytosis of megakaryocytes by monocytes and macrophages.¹⁹ The mechanisms of enhanced platelet consumption in sepsis include ongoing thrombin generation and increased adhesion of platelets to endothelial cells.¹⁹ Diagnosis and therapy should follow the current guidelines.¹⁷ Recommendations for platelet transfusion in these guidelines are derived from those for chemotherapy-induced thrombocytopenia and do not differ from those given in Table 21-2.

DIC

According to the definition of the International Society on Thrombosis and Hemostasis (ISTH), DIC is “an acquired syndrome characterized by the intravascular activation of coagulation with the loss of localization arising from different causes.”²¹ Sepsis, trauma, organ destruction (e.g., due to severe pancreatitis), tumors, and severe hepatic failure²¹ are conditions that are commonly associated with DIC. The consumption of coagulation factors and platelets manifests with typical laboratory findings that are used for a DIC score (Table 21-3). Clinically, patients often present with bleeding, although symptoms due to isolated microthrombi (e.g., digital ischemia) are also possible.

Therapy should be focused on managing the underlying cause of DIC. Patients with mild clotting abnormalities and no evidence of

TABLE 21-3 Diagnostic Scoring System for Disseminated Intravascular Coagulation

1. Risk assessment: Does the patient have an underlying disorder known to be associated with overt DIC?
If yes, proceed with this algorithm
If no, do not use this algorithm
2. Order global coagulation tests (prothrombin time, platelet count, fibrinogen, fibrin-related marker)
3. Score results of global coagulation tests:

| PARAMETER | 0 POINTS | 1 POINT | 2 POINTS |
|-------------------------------|----------------------|-----------------------------------|---------------------|
| Platelets | $>100 \times 10^9/L$ | $<100 \times 10^9/L$ | $<50 \times 10^9/L$ |
| Fibrinogen | $>1.0 \text{ g/L}$ | $<1.0 \text{ g/L}$ | |
| Prothrombin time prolongation | $<3 \text{ s}$ | $\geq 3 \text{ to } <6 \text{ s}$ | $\geq 6 \text{ s}$ |
| D-dimer | $<1 \mu\text{g/mL}$ | $1\text{--}5 \mu\text{g/mL}$ | $>5 \mu\text{g/mL}$ |

4. Calculate score as follows:
 <5 points: suggestive of nonovert DIC, repeat scoring within next 1 to 2 days;
 ≥ 5 points: compatible with overt DIC, repeat scoring daily

Adapted from Toh CH, Hoots WK: SSC on Disseminated Intravascular Coagulation of the ISTH. The scoring system of the Scientific and Standardisation Committee on Disseminated Intravascular Coagulation of the International Society on Thrombosis and Haemostasis: a 5-year overview. *J Thromb Haemost*. 2007 Mar;5(3):604-6. Tab 1.

bleeding require no further treatment when thrombosis prophylaxis is part of the standard therapy. In cases of bleeding or a high bleeding risk, the substitution of coagulation factors and platelets may become necessary. A platelet transfusion trigger of $50 \times 10^9/L$ is recommended in DIC, although this recommendation is expert opinion based and not supported by valid studies.²²

DTP

DTP is the underlying cause in $\approx 10\%$ of thrombocytopenic ICU patients.^{9,19,20} Nonimmunological factors, such as bone marrow depression, are responsible for most cases of DTP. Table 21-4 summarizes the different mechanisms for DTP and the involved drugs.

DTP is rare and clinically manifests with an abrupt platelet count decrease to $<20 \times 10^9/L$. DTP is often accompanied by bleeding complications 5 to 14 days after starting a new drug. The suspected drug should be stopped immediately. Laboratory tests may be performed to support the diagnosis, but they are only provided by specialized laboratories and, with the exception of HIT, are not very sensitive. Thus, a negative test result does not exclude DTP. In contrast, platelet recovery, which usually begins 5 to 7 half-times after cessation of the causative drug, provides sufficient evidence for the diagnosis. Further therapy, which is sometimes necessary in severely bleeding patients, includes platelet transfusion, high doses of intravenous

TABLE 21-4 Mechanisms of the Development of Drug-Induced Thrombocytopenia (Data from^{23,33-35})

| MECHANISM | DESCRIPTION | DRUGS |
|-----------------------------------|--|--|
| Classic drug-dependent antibodies | Drug binds to platelet glycoproteins or antibodies, causes conformational changes thereby allowing antibody binding, resulting in increased platelet destruction by the reticuloendothelial system | Quinine, quinidine, antibiotics (sulfamethoxazole trimethoprim, vancomycin, rifampicin, cephalosporin), antiepileptics (valproate, carbamazepine, phenytoin), diuretics (furosemide, thiazides), ranitidine, nonsteroidal antiinflammatory drugs (diclofenac, ibuprofen) |
| Hapten-induced antibodies | Drug acts as a hapten that binds large molecules (e.g., proteins) on the platelet surface and stimulates antibody production | Penicillin and cephalosporin |
| Fiban-induced antibodies | Drug binds to epitopes on glycoprotein IIb/IIIa receptors on platelets and enhances affinity of preexisting anti-platelet antibodies | Tirofiban and eptifibatide |
| Drug-specific antibodies | Monoclonal antibodies bind to glycoprotein IIb/IIIa receptors on platelets and become targets of naturally occurring antibodies provoking increased platelet destruction | Abciximab |
| Autoantibodies | Platelet-specific autoantibodies are produced in the presence of a drug (exact mechanism unknown) | Procainamide, levodopa, and gold |
| Formation of immune complexes | Drug (e.g., heparin or protamine) binds to platelet factor 4 (PF4) in the circulation, creating complexes that provoke antibody formation. These antibodies bind with their Fab fragment to the drug/PF4 complex and with their Fc fragment to FcγRIIIa receptors on platelets causing platelet activation | Unfractionated heparin, low-molecular-weight heparin, and protamine |
| Bone marrow depression | Toxic bone marrow depression | Chemotherapeutics, linezolid, nonsteroidal anti-inflammatory drugs, and azathioprine |
| Thrombotic microangiopathy | Auto-antibodies against ADAMTS13 are produced in presence of the drug causing ADAMTS13 deficiency | Ticlopidine, clopidogrel, prasugrel, and cyclosporine |
| Unknown | The mechanism is unknown | Other antibiotics (daptomycin, nitrofurantoin), ganciclovir, fluconazole, digoxin, and haloperidol |

immunoglobulin (IVIG)—that is, 1 g/kg body weight on 2 consecutive days, and corticosteroids.²³ The responsible drug should be avoided in the future.

HIT

HIT usually occurs 5 to 10 days after starting treatment with unfractionated or low-molecular-weight heparin. HIT is caused by antibodies directed against a complex of PF4 and heparin (Table 21-4). HIT considerably differs from classic DITP: first, the platelet count is usually $\geq 20 \times 10^9/L$; second, thrombosis (often life-threatening) and not bleeding is the typical clinical manifestation; third, treatment consists not only of stopping heparin but also of starting an alternative anticoagulant—for example, a direct thrombin inhibitor (bivalirudin or argatroban) or the heparinoid danaparoid; fourth, in contrast to classic DITP, re-exposure to heparin can be safe under special circumstances (e.g., during cardiovascular surgery) when antibodies, which usually disappear 50 to 100 days after the acute episode of HIT, are no longer detectable.¹⁴

HIT occurs in 0.5 to 1% of ICU patients.²⁴ However, tests for anti-PF4/heparin antibodies are very sensitive for clinically irrelevant antibodies. Thus, PF4/heparin antibodies are found in up to 50% of ICU patients.²⁵ To reduce the risk of HIT overdiagnosis and to avoid the unnecessary and potentially harmful use of alternative anticoagulants, only patients with at least an intermediate pretest probability of HIT should be tested for anti-PF4/heparin antibodies (i.e., patients with ≥ 4 points on the 4Ts score)¹⁴ (Table 21-5). Although about 2 to 3% of patients with a low 4Ts score have HIT, a low 4Ts score plus a negative PF4/heparin test generally excludes HIT.

Trauma

Trauma is one of the common causes of thrombocytopenia in ICU patients, with a relative incidence of 7.5%.^{9,19,20} The mechanisms of

coagulopathy in trauma consist of the loss and consumption of coagulation factors and platelets, hyperfibrinolysis, and platelet dysfunction.²⁶ Therapy for volume deficiency may cause hemodilution and hypothermia and sometimes acidosis, all enhancing the bleeding risk.

In contrast to other coagulation factors (e.g., fibrinogen), blood loss must be massive before the platelet count falls below critical values. For example, in otherwise healthy patients undergoing elective surgery, the blood loss was 230% of the estimated blood volume before platelets decreased to $<50 \times 10^9/L$.²⁷ Therefore, platelet transfusion is probably only required in cases of severe bleeding and massive blood loss. The current European guideline recommends that platelets be given to maintain a platelet count of $>50 \times 10^9/L$ in all trauma patients and $>100 \times 10^9/L$ in patients with ongoing bleeding and/or traumatic brain injury.²⁸

ITP

ITP is “an autoimmune disorder characterized by immunologic destruction of otherwise normal platelets most commonly occurring in response to an unknown stimulus.”²⁹ Onset of ITP is extremely rare in adult ICU patients; however, it is possible that an ITP patient requires admission to the ICU because of bleeding. In this case, IVIG (≈ 1 g/kg body weight) together with corticosteroids should be administered.²⁹ Platelet transfusions can become necessary in cases of severe bleeding.

Thrombotic Microangiopathies (TMAs)

TMAs comprise a series of hereditary or acquired syndromes—namely, thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), and the HELLP syndrome (characterized by hemolysis, elevated liver enzymes, and low platelets in pregnancy). All have microangiopathic hemolytic anemia, thrombocytopenia, and organ injury in common³⁰; however, their underlying mechanisms differ.³⁰ TTP is caused by hereditary or acquired ADAMTS13 deficiency.

TABLE 21-5 The 4Ts Score for Estimating the Pretest Probability of Heparin-Induced Thrombocytopenia¹⁴

| | POINTS (0, 1, OR 2 FOR EACH OF THE FOUR PARAMETERS; MAXIMUM POINTS = 8) | | |
|--|---|--|---|
| | 2 | 1 | 0 |
| Thrombocytopenia (acute) | >50% platelet count fall to nadir $\geq 20 \times 10^9/L$ | 30%-50% platelet count fall; or nadir $10-19 \times 10^9/L$ | <30% platelet count fall; or nadir $\leq 10 \times 10^9/L$ |
| Timing of fall in platelet count or other sequelae | Onset day 5-10 or <1 day (if heparin exposure within 30 days) | >Day 10, timing unclear, or <day 1 with recent heparin 31-100 days | Platelet count fall <day 4 (without recent heparin exposure) |
| Thrombosis or other sequelae | New thrombosis; skin necrosis; post-heparin bolus acute systemic reaction | Progressive or recurrent thrombosis; erythematous skin lesions; suspected thrombosis—not confirmed | None |
| Other cause for thrombocytopenia | No other cause for platelet count fall is evident | Possible other cause is evident | Definite other cause is present |

Pretest probability score: 6–8 = High; 4–5 = Intermediate; 0–3 = Low

Hereditary TTP requires immediate plasma infusion (to replace ADAMTS13). In acquired TTP, plasma exchange (for the additional elimination of supposed anti-ADAMTS13 antibodies) combined with immunosuppressive therapy is essential to improve the patient's prognosis from $\approx 10\%$ survival to nearly 80%.³⁰ A special form of TTP in ICU patients is post-surgery TTP, which is typically nonimmune mediated and caused by the reduced activity of ADAMTS13 and concomitantly high von Willebrand factor levels.

Typical HUS is induced by bacteria (most often *Escherichia coli* strains producing Shiga toxin) and requires supportive therapy. Plasma exchange has not been shown to be effective. Atypical HUS is a hereditary disorder in patients with various mutations in proteins regulating the activity of the complement system.³¹ The inhibition of complement with eculizumab is the treatment of choice.

Thrombocytopenia in TMA is caused by increased platelet consumption resulting from excessive platelet activation and thrombus

formation in the microcirculation.³¹ Therefore, platelet transfusion is often avoided but remains justified in patients with clinically significant bleeding.

PTP

PTP presents very similarly to DITP—that is, with an abrupt fall in platelet count to $<20 \times 10^9/L$. PTP occurs 7 to 14 days after the transfusion of allogeneic blood products. Patients developing this rare complication are typically women older than 50 years, who were preimmunized during pregnancy against human platelet antigens (HPA; usually HPA1a). The transfusion of HPA1a-positive blood boosts the alloantibodies, which broaden their specificity by an immunologic phenomenon called antigen spreading, and also destroy autologous platelets. High-dose IVIG is the treatment of choice.

Disorders of clotting and hemostasis are common in the intensive care unit (ICU) setting, especially among patients with systemic inflammatory response syndrome (SIRS), sepsis, postoperative inflammatory states, and trauma.¹ Nearly all patients with a systemic inflammatory state fall somewhere on the broad spectrum of disordered hemostasis, ranging from minimally detectable dysfunction with no overt clinical manifestations to disseminated intravascular coagulation (DIC).^{2,3} Up to 28% of ICU patients have coagulation dysfunction, as evidenced by the prolongation of prothrombin time (PT) or the activated partial thromboplastin time (aPTT).¹ Detecting coagulopathy has important implications in the trauma population. In one study, 28% of patients presented with prolonged PT and 8% presented with prolonged aPTT; the presence of these findings increased the adjusted odds of mortality in these patients by 35% and 326%, respectively.⁴ In sepsis, mortality rates for patients with DIC range from 40% to 50%, and the presence of DIC confers a significantly higher risk of mortality.^{2,5}

In this chapter, we will focus on the cascade of soluble clotting factors and their associated natural anticoagulant proteins: the system of secondary hemostasis.⁶ Disorders of primary (cellular) hemostasis, including thrombocytopenia, are addressed in other chapters.⁷ We will utilize the SIRS/sepsis patient as a prototypical model for ICU coagulopathy, although there are certainly other populations warranting specific approaches, such as patients with trauma, cancer, or cirrhosis.

MECHANISMS OF HEMOSTASIS

Historically, students have been taught that coagulation comprises two cascading pathways of proteases that converge at the conversion of factor X to factor Xa: the intrinsic and extrinsic pathways (Fig. 22-1). Once active, factor Xa cleaves prothrombin (factor II) to thrombin, which performs the penultimate event of cleaving soluble fibrinogen to fibrin. Fibrin polymers are then further cross-linked by factor XIII, thereby generating a “stable clot.” The formation of fibrin serves not only to provide hemostasis but also aids in host defense by “walling off” pathogenic microbes.⁶ Counteracting these procoagulant mechanisms are several natural anticoagulants that minimize the unregulated generation of clots: antithrombin III, its co-factor heparan; protein C, its co-factor protein S; and tissue factor pathway inhibitor (TFPI). These factors act at various locations along the coagulation pathways to inhibit the coagulation process (Fig. 22-1). Clot formation is further regulated by fibrinolysis, a function of the enzyme plasmin, which breaks down polymerized fibrin into D-dimers. The overall control of hemostasis reflects a balance between pro- and anticoagulant elements.^{6,8}

Our contemporary perspective of the coagulation mechanism no longer equally weighs the extrinsic and intrinsic cascades in the generation of thrombus. Rather, the extrinsic pathway is now regarded as the main initiator of coagulation, whereas the intrinsic pathway serves to amplify the process via the mechanisms of intercommunication between the two pathways and feedback loops.⁸ Examples of this include the activated form of factor VII serving to activate both factor X and factor IX and the activation of factor XI and factor VIII by thrombin.⁸

INFLAMMATION AND THE DEVELOPMENT OF COAGULOPATHY

Immunity, inflammation, and coagulation are intimately intertwined, and although these systems historically have been considered in isolation, each possesses the capacity to augment or modulate the others. An inflammatory state, such as sepsis, tips the balance between anticoagulant forces and procoagulant forces in the direction of clot formation, predominantly by increasing the elaboration of tissue factor (TF) and its systemic exposure to the circulating blood.^{2,3} As most TF is produced by cells not normally in direct contact with the blood, the disruption of endothelial barriers due to trauma or inflammation increases the exposure of the blood to TF, thereby initiating coagulation. In sepsis, the release of proinflammatory cytokines, such as interleukin (IL)-6, causes monocytes, neutrophils, and endothelial cells that do not usually express TF to begin doing so.³

In states of systemic inflammation, decreased levels of natural anticoagulants (antithrombin, protein C, and TFPI) further exacerbate the imbalance and augment the expression of a procoagulant phenotype. Several biological mechanisms, including the consumption of existing factors, impaired production of new anticoagulant molecules, and degradation by neutrophil elastase of existing anticoagulant molecules, underlie the loss of anticoagulation.³ The summation of these events promotes excessive and unregulated clot formation and the further depletion of clotting factors.⁹ A vicious cycle now ensues. Compounding the issue of decreased natural anticoagulant levels is the loss of endothelial-bound thrombomodulin via endothelial shedding of thrombomodulin into the circulation,¹⁰ a process that interferes with the activation of protein C and thereby exacerbates the effects of protein C depletion.

The activation of fibrinolytic pathways occurs early and concomitant with the development of the septic procoagulant state, through the release of tissue plasminogen activator (tPA) and urokinase plasminogen activator from the endothelium in response to inflammatory cytokines, notably tumor necrosis factor (TNF)- α and IL-1 β .³ This increase in plasminogen activators is later accompanied by an increase in circulating plasminogen activator inhibitor type 1 (PAI-1), which blocks fibrinolysis and propagates microvascular thrombosis.³ Elevated levels of PAI-1 have been associated with worse outcomes in sepsis, but its overall role may be protective since mice deficient in PAI-1 show increased susceptibility to a variety of bacterial infections.¹¹

The coagulation and inflammatory cascades are linked by the activation of transmembrane cell receptors known as protease-activated receptors, which are found on vascular endothelial cells, mononuclear cells, platelets, fibroblasts, and smooth muscle cells.^{3,12} These receptors are cleaved and activated by coagulation cascade proteases, thrombin, and the TF-VIIa complex.^{3,12} Activation promotes inflammation by increasing the production of proinflammatory cytokines and cellular adhesion molecules.^{3,11} It is interesting to note that various components of the coagulation system, including TFPI, prothrombin, and factor X, have been found to have antimicrobial properties.¹¹ Coagulation, hemostasis, and the immune system are also linked by neutrophil extracellular traps (NETs).^{11,13} Responding to exposure to invading pathogens, neutrophils release a backbone of DNA stippled with

FIGURE 22-1 ■ Schematic of the Coagulation System. Further amplification of the intrinsic pathway occurs via thrombin-mediated activation of factor XI and factor VIII.

various bactericidal components, including histones, elastase, cathepsin G, and other components of azurophilic granules. NETs function by facilitating the extracellular trapping of bacteria.¹³ NET formation in sepsis has been implicated in the propagation of microvascular thrombosis, as the NETs can trap erythrocytes and platelets.^{11,13} Intravascular trapping of these blood cells can promote DIC by creating surfaces on which coagulation reactions can proceed.¹¹

DIAGNOSTIC METHODS AND CLINICAL MANIFESTATIONS

The clinical practice of assessing and monitoring coagulation status is achieved by testing the PT and activated partial thromboplastin time aPTT as measures of the extrinsic and intrinsic pathways, respectively (Table 22-1). Classically, PT measurements were used to monitor the effectiveness of warfarin for therapeutic anticoagulation, and aPTT measurements were used for monitoring heparin therapy. Use of the international normalized ratio (INR) has standardized testing of the extrinsic pathway, as unadjusted PT values may vary slightly among different clinical sites due to variations in reagents.¹⁴ Recent data have challenged the value of measuring aPTT and/or PT/INR for making the diagnosis and managing the treatment of coagulopathy. Critics highlight that the tests were designed for the management of warfarin and heparin therapy,^{14,15} and little evidence exists to support the use of PT, INR, or aPTT for guiding the treatment of coagulopathy.¹⁵

The development of newer anticoagulant therapeutics has necessitated the development of assays to assess their activity. Agents such as low-molecular-weight heparin (enoxaparin) and direct Xa inhibitors (e.g., fondaparinux) can be monitored using an anti-Xa activity assay. However, the favorable linear, and thus predictable, dose-response characteristics for these agents make laboratory monitoring less needed.¹⁴ Other less utilized tests include the Russell's viper venom assay (final common pathway) and the thrombin time and reptilase assays (sufficiency and functional status of fibrinogen).¹⁴

Fibrinogen levels can be measured directly, and this parameter may be a useful one to follow when there is a high suspicion of DIC. However, total fibrinogen levels may not be an optimal test; sufficient concentrations of fibrinogen, an acute phase reactant, can exist in the context of DIC and sepsis.¹⁶ Similarly, increased levels of D-dimer and/or fibrin/fibrinogen degradation are nonspecific findings in the ICU setting, as circulating levels of these proteins can be increased for a variety of reasons, especially in surgical or injured patients.^{14,16}

TABLE 22-1

Causes of Increased Prothrombin Time/International Normalized Ratio (PT/INR) and/or Activated Partial Thromboplastin Time (APTT)

INCREASED PT/INR—DEFECT IN EXTRINSIC PATHWAY

Deficiency or inhibitor of factor VII
Early warfarin (Coumadin) therapy
Early liver disease

INCREASED APTT—DEFECT IN INTRINSIC PATHWAY

Deficiency or inhibitor of factors XII, XI, IX, or VIII
Heparin (though usually affects PT as well)
Liver disease (though usually affects PT as well)
Lupus anticoagulant (may affect PT as well)

INCREASED PT/INR AND APTT—DEFECT IN COMMON PATHWAY OR COMBINED DEFECT IN EXTRINSIC AND INTRINSIC PATHWAYS

Heparin (all serine proteases affected, especially II and X)
Disseminated intravascular coagulation (all factors, including pro- and anticoagulants, affected)
Liver disease (all factors except VIII affected)
Warfarin (factors II, VII, IX, and X affected)
Vitamin K deficiency (factors II, VII, IX, and X affected)
Direct thrombin inhibitors
Lupus anticoagulant

Modified from: Rizoli S, Aird WC. Coagulopathy. In: Vincent JL, Abraham E, Moore FA, et al., editors. *Textbook of Critical Care*. 6th ed. Philadelphia: Elsevier; 2011.

DIC results in widespread activation of the coagulation system with the deposition of fibrin primarily in small-caliber vessels.¹⁷ Significant end-organ damage, including encephalopathy, acute lung injury, liver failure, and acute renal failure, can ensue.¹⁷ The diagnosis is difficult as the process may mimic other thrombotic microangiopathies (thrombotic thrombocytopenic purpura [TTP], hemolytic uremic syndrome [HUS], and *hemolysis, elevated liver enzymes, and low platelet count* [HELLP syndrome] associated with pregnancy), heparin-induced thrombocytopenia (HIT), and liver failure.^{17,18} No single laboratory test for DIC exists, but the syndrome is usually characterized by a low platelet count, prolonged PT and aPTT tests, increased fibrin degradation products, and decreased levels of natural anticoagulants.¹⁸ Two major scoring systems for the diagnosis of DIC have been created by the International Society on Thrombosis and Hemostasis (ISTH) and the Japanese Association for Acute Medicine (JAAM).¹⁹⁻²¹ The ISTH criteria take into account the platelet count, PT, fibrinogen level, and fibrin degradation product level, while the JAAM DIC scoring system awards points based upon the presence of SIRS criteria, prolonged PT, fibrin/fibrinogen degradation product level, and platelet count (Table 22-2).¹⁹⁻²¹

Less commonly tested pro- and anticoagulant laboratory values in septic patients that are currently not considered in available DIC scoring systems include the levels of protein C and protein S, antithrombin, TFPI, and PAI-1, as well as circulating plasma microparticle levels, and various other experimental markers.^{18,22} Markers like antithrombin and activated protein C are more readily testable than other more experimental markers but are nonspecific as they are decreased in SIRS, particularly sepsis.²³ Endothelial-derived procoagulant microparticles (lipid vesicles with proinflammatory and procoagulant properties released from stressed cells) have been shown to be associated with the development of DIC in septic patients and may represent a new biomarker or potential therapeutic target in sepsis-induced coagulopathy.^{11,13,22,24}

Finally, viscoelastic analysis of coagulation using thromboelastography (TEG) or rotational thromboelastometry (ROTEM) represents a relatively newer method of assessing coagulation status. These tests can identify both hyper- and hypocoagulable states.²⁵ Results from these studies can be visualized in real time, observing the clot

TABLE 22-2 Disseminated Intravascular Coagulation Scoring Systems**INTERNATIONAL SOCIETY ON THROMBOSIS AND HEMOSTASIS (ISTH) OVERT DIC SCORING SYSTEM**

Patient must have an underlying disorder known to be associated with overt DIC. Points assigned based on the following laboratory values:

- Platelet count ($>100 = 0$; $<100 = 1$; $<50 = 2$)
- Elevated fibrin-related marker (e.g., fibrin degradation products) (no increase = 0; moderate increase = 2; strong increase = 3)
- Prothrombin time (<3 seconds = 0; >3 seconds but <6 seconds = 1; >6 seconds = 2)
- Fibrinogen level (>1 g/L = 0; <1 g/L = 1)

Total score ≥ 5 compatible with overt DIC, repeat scoring daily

Score < 5 suggestive (but not affirmative) for nonovert DIC; repeat scoring next 1-2 days

JAPANESE ASSOCIATION FOR ACUTE MEDICINE DIC SCORING SYSTEM

Points assigned based on the following criteria:

- Systemic inflammatory response syndrome criteria ($\geq 3 = 1$; $0-2 = 0$)
- Platelet count (<80 or $>50\%$ decrease within 24 hours = 3; ≥ 80 and <120 or $>30\%$ decrease within 24 hours = 1; $\geq 120 = 0$)
- Prothrombin time (value of patient/normal value) ($\geq 1.2 = 1$; $<1.2 = 0$)
- Fibrin/fibrinogen degradation products (≥ 25 mg/L = 3; ≥ 10 and <25 mg/L = 1; <10 mg/L = 0)

Total score ≥ 4 compatible with a diagnosis of DIC

formation/dissolution curve as the clot forms and then undergoes fibrinolysis. These methods assess whole clot formation and dissolution rather than analyzing only one component of the coagulation system. Furthermore, the transfusion of specific blood components can be directed based upon TEG or ROTEM parameters. The presence of a hypocoagulable TEG profile at the time of admission was predictive of mortality in patients with severe sepsis, and the degree of hypocoagulability was correlated with organ failure severity.^{18,25} TEG/ROTEM results are usually quickly available as point-of-care testing and are gaining popularity in the clinical assessment of coagulopathy.

TREATMENT OF COAGULOPATHY

The primary treatment for any form of coagulopathy is to correct the underlying cause. In the context of sepsis, treatment of the underlying cause involves the administration of antibiotics, source control, and supportive measures, as necessary. Transfusion of blood products are reserved for patients who are actively bleeding or undergoing a procedure with a high risk of bleeding. Abnormal laboratory parameters alone are not an indication for blood product administration in the absence of hemorrhage or anticipated procedures or surgery.¹⁸ If transfusion is deemed necessary, a variety of therapeutic options exist. Fresh frozen plasma (FFP) contains all of the circulating coagulation factors and remains the first-line treatment of hypocoagulability.¹⁶ The PROPPR trial examined the transfusion ratio of plasma to packed red blood cells (PRBC) in massively transfused trauma patients and found that transfusing platelets, FFP, and PRBC in a 1:1:1 ratio was superior for achieving hemostasis and preventing death due to exsanguination in the first 24 hours after trauma as compared to a 1:1:2 ratio (platelets:plasma:PRBC).²⁶ The study noted small improvements in 24-hour and 30-day mortality rates in patients receiving 1:1:1 transfusion ratios, but these differences were not statistically significant.

Cryoprecipitate contains fibrinogen, von Willebrand factor, factor VIII, and factor XIII in a concentrated solution for targeted factor replacement. Prothrombin complex concentrate (PCC) contains

TABLE 22-3 FDA-Approved Fractionated Plasma Products for Treatment of Coagulopathic Hemorrhage**FACTOR VIIA (RECOMBINANT), (NOVOSEVEN, NOVOSEVEN RT)**

Indicated for treatment or prevention of bleeding in patients with hemophilia A or B with inhibitors, acquired hemophilia, or congenital FVII deficiency.

FACTOR VIII (RECOMBINANT), (AKA ANTIHEMOPHILIC FACTOR, VARIOUS BRAND NAMES)

Indicated for patients with hemophilia A for prevention or control of bleeding episodes.

FACTOR VIII/VON WILLEBRAND COMPLEX (HUMAN), (HUMATE-P, ALPHANATE, WILATE)

For treatment of bleeding and perioperative prevention of bleeding in patients with von Willebrand disease.

FACTOR IX (RECOMBINANT), (ALPROLIX, BENEFIX, RIXUBIS)

For treatment of bleeding, prophylaxis, and perioperative prevention of bleeding in patients with hemophilia B.

FACTOR IX COMPLEX, (PROFILNINE SD)

Contains factor IX, factor II, factor X, and low levels of factor VII. For prevention and control of bleeding in patients with hemophilia B.

FACTOR XIII A-SUBUNIT (RECOMBINANT), (TRETTEIN)

Indicated for prophylaxis of bleeding in patients with congenital factor XIII A-Subunit deficiency.

FACTOR XIII CONCENTRATE (HUMAN), (CORIFACT)

Indicated for prophylaxis and perioperative management of bleeding in patients with congenital factor XIII deficiency.

FIBRINOGEN CONCENTRATE (HUMAN), (RIASTAP)

For treatment of acute bleeding episodes in patients with congenital fibrinogen deficiency.

PROTHROMBIN COMPLEX CONCENTRATE (HUMAN), (KCENTRA)

Contains factor II, factor VII, factor IX, factor X, protein C, and protein S. For urgent reversal of acquired coagulation factor deficiency induced by vitamin K antagonist therapy in adults with acute major bleeding.

ANTI-INHIBITOR COAGULANT COMPLEX (HUMAN), (FEIBA NF)

Contains factor II, factor IX, factor X, factor VIIa, and factor VIII coagulant antigen. Indicated for use in patients with hemophilia A and B with inhibitors for prophylaxis, perioperative management, and control of bleeding episodes.

factors II, VII, IX, and X and requires infusion of a smaller volume of fluid to effectively reverse warfarin-induced anticoagulation or replenish specific factor deficiencies. PCC may also be useful for reversing anticoagulation caused by treatment with direct factor Xa inhibitors like rivaroxaban and apixaban.^{27,28} The newer generation oral anticoagulants, including dabigatran, rivaroxaban, and apixaban, present a challenge for the reversal of coagulopathy, as no specific antidotes for any of these drugs are currently available. The reversal of rivaroxaban, but not dabigatran, was accomplished in a study of healthy volunteers using PCC.²⁸ Specific factor concentrates such as recombinant factor VIIa are sometimes used in an off-label fashion for various causes of coagulopathy, often as a last-ditch effort to control life-threatening hemorrhage (Table 22-3).¹⁶

Protamine is a specific reversal agent for unfractionated heparin, although multiple side effects have been reported, including hypotension, pulmonary vasoconstriction, and anaphylaxis.²⁷ The use of anti-fibrinolytic drugs, such as ϵ -aminocaproic acid or tranexamic acid (TXA), is warranted if hyperfibrinolysis is present. TXA has been

studied extensively in trauma victims.^{16,27,29} The CRASH-2 study analyzed data from over 20,000 patients presenting with significant hemorrhage within 8 hours of injury and found decreased mortality due to hemorrhage as well as decreased all-cause mortality when TXA was given within 3 hours of injury.²⁹

Anticoagulant therapy for the treatment of DIC has received a great deal of attention in the past two decades. Some experts advocate the use of heparin in low-grade DIC to treat and prevent further thrombosis.¹⁸ The infusion of recombinant human activated protein C (drotrecogin alfa) was studied in the PROWESS, ADDRESS, and PROWESS-SHOCK trials.^{23,30,31} Results from the most recent trial of drotrecogin alfa, the PROWESS-SHOCK trial, showed no improvement in overall mortality compared to the placebo, and the drug was withdrawn from the market in 2011. Other therapies that have been studied include human recombinant TFPI (tifacogin) and antithrombin.³²⁻³⁶ Thrombomodulin has yielded promising results in early clinical trials and is currently under further investigation.³⁷

SUMMARY

- Coagulopathy is a common finding in the ICU with a wide range of severities at presentation.
- Increases in available tissue factor, decreases in natural anticoagulants, and impairment of fibrinolysis all contribute to the procoagulant state in sepsis.
- Inflammation, the immune system, and the coagulation system are intimately associated.
- No single laboratory test is diagnostic of DIC, but predictive scoring systems are available.
- TEG/ROTEM are good methods for point-of-care assessment of coagulation function.
- The mainstay for treatment of coagulopathy is treating the inciting condition (e.g., sepsis).
- Ongoing trials are investigating the role of anticoagulant therapy in the treatment of sepsis.

Bilirubin is a byproduct of heme metabolism. Heme is largely derived from the hemoglobin in senescent red blood cells and is oxidized in the spleen, liver, and other organs by two isoforms of the enzyme heme oxygenase, in the presence of nicotinamide adenine dinucleotide phosphate (NADPH) and molecular oxygen, to form biliverdin, carbon monoxide, and iron.¹ Subsequently, biliverdin is converted into bilirubin by the phosphoprotein, biliverdin reductase, which also uses NADPH as a cofactor.

Bilirubin is a lipophilic molecule. To be excreted, bilirubin that is produced in extrahepatic organs is bound to albumin and transported to the liver. The liver takes up the bilirubin-albumin complex through an albumin receptor. Bilirubin, but not albumin, is transferred across the hepatocyte membrane and transported through the cytoplasm to the smooth endoplasmic reticulum bound primarily to ligandin or Y protein, a member of the glutathione S-transferase gene family of proteins. Within hepatocytes, bilirubin is converted to water-soluble derivatives, bilirubin monoglucuronide and bilirubin diglucuronide, by the enzyme uridine diphosphate-glucuronosyl transferase. These conjugated forms of bilirubin are secreted across the canalicular membrane into the bile via an energy-dependent process. Conjugated bilirubin is excreted in the bile into the intestine, where it is broken down by the gut microflora into urobilinogen and stercobilin.

Total serum bilirubin consists of an unconjugated fraction and a conjugated fraction. The conjugated forms of bilirubin exist both freely in the serum and bound covalently to albumin. Conjugated bilirubin is water soluble and reacts directly to certain dyes added to the serum specimen. The unconjugated bilirubin does not react with the colorimetric reagents until a solvent is added. Accordingly, the conjugated and unconjugated forms of bilirubin are sometimes referred to as “direct” and “indirect” bilirubin. The sum of these two measurements is the “total” bilirubin. The normal total bilirubin concentration in adults is less than 18 $\mu\text{mol/L}$ (1.0 mg/dL). Although any total bilirubin concentration higher than the upper limit of normal constitutes hyperbilirubinemia, jaundice (i.e., yellow discoloration of the sclerae, mucous membranes, and skin) is usually not clinically apparent unless the serum total bilirubin level is greater than 50 $\mu\text{mol/L}$ (2.8 mg/dL). Unconjugated or indirect hyperbilirubinemia is present when the total serum bilirubin concentration is above the upper limit of normal and less than 15% of the total is in the direct or conjugated form.

■ DIFFERENTIAL DIAGNOSIS

The multitude of diagnoses depicted in [Box 23-1](#) divides the causes of hyperbilirubinemia into two large groups according to whether the predominant abnormality is an increase in the circulating concentration of unconjugated (indirect) bilirubin or an increase in the concentration of conjugated (direct) bilirubin. Although this classification scheme is useful under some circumstances, many of the diagnoses listed in [Box 23-1](#) are extremely rare and highly unlikely to be encountered by the intensivist caring for critically ill (adult) patients. A more useful classification scheme is depicted in [Box 23-2](#). In this scheme, the causes of jaundice are grouped into three primary categories: extrahepatic obstruction to bile flow, increased bilirubin production, and impaired excretion secondary to hepatocellular necrosis and/or intra-

hepatic cholestasis and hepatitis. It is common for multiple mechanisms to be involved simultaneously.

Hyperbilirubinemia occurs frequently in critically ill patients and is an independent risk factor for an unfavorable outcome.^{2,3} In a retrospective study of adult patients admitted to an intensive care unit (ICU) with severe sepsis or septic shock, the mortality rate was 12%, 24%, and 42% for individuals with a peak serum bilirubin concentration during the first 72 hours that was ≤ 1 , 1.1 to 2, or >2 mg/dL, respectively.⁴ In another retrospective study, hyperbilirubinemia was a significant risk factor for the development of the acute respiratory distress syndrome (ARDS) among patients admitted to an ICU with sepsis.⁵ In one widely cited study, hyperbilirubinemia occurred in 217 of 2857 trauma patients who had an Injury Severity Score greater than 14 and survived for longer than 48 hours after admission to the hospital.⁶ In this study, hyperbilirubinemia was significantly associated with an increased length of stay in the ICU and death. Hyperbilirubinemia is also common in ICU patients who are recovering from cardiac surgery.^{7,8} In this category of ICU patients, risk factors for the development of hyperbilirubinemia include prolonged cardiopulmonary bypass time, prolonged aortic cross-clamp time, and the use of an intraaortic balloon pump.⁸

Determining the cause of new-onset hyperbilirubinemia is important when managing ICU patients because some problems can be corrected. Exclusion of a mechanical cause for jaundice (e.g., obstruction of the common bile duct due to choledocholithiasis or stricture) assumes the highest priority because failure to correct this type of problem in a timely fashion can lead to serious morbidity or even mortality.

Iatrogenic injuries to the common bile duct are fortunately quite rare. Damage to the biliary tree, stricture of biliary anastomoses, and retained stones after cholecystectomy or common bile duct exploration present as hyperbilirubinemia and elevated circulating levels of alkaline phosphatase or gamma-glutamyl transpeptidase. Most often the diagnosis is made by detecting the dilation of intrahepatic and extrahepatic bile ducts using ultrasonography.

By exceeding the capacity of the liver to conjugate and excrete bilirubin into the bile, hemolysis can result in jaundice. However, the liver can excrete approximately 300 mg/day of bilirubin,⁹ and therefore, clinically significant hyperbilirubinemia is only apparent if the rate of hemolysis (i.e., the number of red blood cells lysed per unit time) is fairly rapid. Approximately 10% of the erythrocytes in an appropriately cross-matched unit of packed red blood cells undergo rapid hemolysis, yielding about 250 mg of bilirubin.¹⁰ Accordingly, transfusion of a single unit of packed red blood cells is not likely to increase the total serum bilirubin concentration. However, transfusion of multiple units of blood over a short period almost inevitably leads to some degree of hyperbilirubinemia, particularly if hepatic functionality is already impaired. Other common causes of acute hemolysis in ICU patients include sickle cell disease, immune-mediated hemolytic anemia, and disseminated intravascular coagulation.

Any condition that leads to extensive hepatocellular damage will increase the circulating total bilirubin concentration. Conditions in this category that are commonly encountered in ICU patients include viral hepatitis, “shock liver,” alcoholic hepatitis, and hepatocellular injury induced by drugs, especially acetaminophen.¹¹ In most forms of jaundice due to hepatic inflammation or hepatocellular damage,

[†]Deceased.

BOX 23-1**Differential Diagnosis of Hyperbilirubinemia**

- A. Unconjugated hyperbilirubinemia
 - 1. Overproduction of bilirubin
 - a. Hemolysis, intravascular: disseminated intravascular coagulation
 - b. Hemolysis, extravascular
 - i. Hemoglobinopathies
 - ii. Enzyme deficiencies (e.g., glucose-6-phosphate dehydrogenase deficiency)
 - iii. Autoimmune hemolytic anemias
 - c. Ineffective erythropoiesis
 - d. Resorption of hematoma
 - e. Massive transfusion
 - 2. Hereditary unconjugated hyperbilirubinemia
 - a. Gilbert's syndrome (autosomal dominant)
 - b. Crigler-Najjar syndrome type I (autosomal recessive)
 - c. Crigler-Najjar syndrome type II (autosomal dominant)
 - 3. Drugs
 - a. Chloramphenicol: neonatal hyperbilirubinemia
 - b. Vitamin K: neonatal hyperbilirubinemia
 - c. 5 β -Pregnane-3 α , 20 α -diol: cause of breast milk jaundice
- B. Conjugated hyperbilirubinemia
 - 1. Inherited disorders
 - a. Dubin-Johnson syndrome (autosomal recessive)
 - b. Rotor syndrome (autosomal recessive)
 - 2. Hepatocellular diseases and intrahepatic causes

circulating levels of transaminases are elevated to a greater extent than the total bilirubin concentration. Making a diagnosis of acetaminophen overdose early is extremely important because specific therapy using N-acetylcysteine can be lifesaving.¹¹

Efforts to understand the pathophysiological mechanisms responsible for cholestatic jaundice due to sepsis have largely focused on lipopolysaccharide (LPS)-induced alterations in the function and expression of various bile acid transporters.¹²⁻¹⁴ Nevertheless, another factor that likely contributes to the development of intrahepatic cholestasis is the back-leakage of bile from the canalicular spaces into the sinusoids.¹⁵

Total parenteral nutrition (TPN) is associated with the development of hyperbilirubinemia.¹⁶ The basis for TPN-induced cholestasis is thought to be multifactorial. Prolonged bowel rest and ileus may promote bacterial overgrowth and increased translocation of LPS into the portal vein on this basis. Phytosterols are present in the lipid emulsions used for TPN and have been associated with cholestasis, especially in premature infants.¹⁷ Results from two retrospective studies suggest that the administration of more than 1 g/kg/day of lipid emulsion is associated with an increased incidence of hepatocellular dysfunction.^{18,19} However, these data were derived from studying patients receiving TPN at home for prolonged periods and may not apply to ICU patients. In any case, TPN is associated with the development of jaundice and hepatocellular damage. Accordingly, except in rare cases, the majority of ICU patients are better served by receiving enteral rather than parenteral nutrition.

Gastrointestinal (GI) bleeding is a common reason for admission to the intensive care unit (ICU). Patients often present in various stages of hemodynamic instability and the location of the hemorrhage may not be certain at the time of initial presentation. Morbidity and mortality from GI bleeding have remained relatively stable even though management has improved. This is due to an aging population presenting with an increasing number of comorbidities and the use of newer anticoagulant medications that can complicate management. The most common causes of significant GI bleeding are peptic ulcer disease (PUD), esophageal varices, and diverticulosis.¹

Patients with significant active GI bleeding, hemodynamic instability, or significant comorbid conditions should be admitted to an ICU for monitoring. Critically ill patients presenting with GI bleeding benefit from having a multidisciplinary team of doctors, including an intensivist, a gastroenterologist, a radiologist, and a surgeon.

■ UPPER GI HEMORRHAGE

Epidemiology

Upper GI (UGI) bleeding is more common than lower GI (LGI) bleeding.¹ UGI bleeding in the United States results in more than 400,000 admissions per year, and a significant number of these cases are admitted to the ICU.² The risk of significant GI bleeding increases with age; accordingly, as the number of elderly people in the population increases, admissions for GI hemorrhage are expected to rise.^{3,4} Patients presenting with acute UGI bleeding have a high risk of mortality (4.5%-8.2%).⁵ Patients that develop UGI bleeding while in the hospital have an increased risk of mortality due to the presence of comorbid conditions.^{6,7,8} Approximately 80% of mortality in cases of GI hemorrhage is attributed to the exacerbation of other illnesses.⁹

Acute UGI bleeding is defined as blood loss that occurs proximal to the ligament of Treitz. UGI bleeding can present with coffee ground emesis, hematemesis, melena, or even hematochezia if bleeding is rapid.¹⁰ Factors predictive of a UGI bleeding source include a history of melena, the ratio of blood urea nitrogen (BUN) to serum creatinine concentration of >30 and coffee ground material on nasogastric (NG) tube lavage.⁵ UGI bleeding is classified as derived from a variceal or a nonvariceal source and about 80%-90% of episodes are nonvariceal. The most common causes of nonvariceal bleeding are PUD, esophagitis, and Mallory-Weiss tears. Common causes of PUD include nonsteroidal antiinflammatory drug (NSAID) use and *Helicobacter pylori* infection.¹¹ Variceal hemorrhage is seen in patients with cirrhosis. The presence of varices increases with worsening liver failure and varices are present in as many as 85% of patients with the advanced ("Child C") disease. The most important predictor of variceal hemorrhage is the size of the varix.¹²

Patient Approach

Key steps in the management of any patient with GI hemorrhage include the following: 1) resuscitation; 2) correction of coagulopathy, thrombocytopenia, and platelet dysfunction, if present; 3) diagnosis; 4) medical, endoscopic, or invasive radiologic or surgical intervention, if indicated (Fig. 24-1).

Resuscitation

The priority in the critically ill patient presenting with GI bleeding is establishing intravenous (IV) access and resuscitating the patient to

achieve hemodynamic stability. Large bore IV access catheters capable of supporting the rapid infusion of asanguinous fluids and blood products should be inserted. Infusion of a crystalloid solution should be started initially and followed by an infusion of packed red blood cells (PRBC) or other blood products, as indicated. Endotracheal intubation for airway protection should be considered early to reduce the risk of aspiration. The patient should be typed and crossed for blood transfusion. Laboratory studies should be obtained consisting of complete blood count (CBC), electrolytes, and coagulation profile. In acutely hemorrhaging patients, the initial blood hemoglobin concentration may not accurately reflect the extent of blood loss. Accordingly, blood hemoglobin concentration should be monitored frequently.

Transfusion should focus on maintaining a hemoglobin concentration greater than 7 g/dL. Studies have shown improved outcomes in patients with a threshold for transfusion of 7 g/dL rather than a transfusion trigger of 9 g/dL.¹³ In patients with brisk bleeding, a massive transfusion protocol should be performed by giving equal amounts of PRBC, fresh frozen plasma (FFP), and platelets to prevent development or worsening of coagulopathy due to dilution of clotting factors. The classification of anemia is also important as patients with acute GI bleeding have normocytic red blood cells whereas patients with chronic blood loss typically have microcytic red blood cells.

Correction of Coagulopathy

If the international normalized ratio (INR) is prolonged (due to treatment with warfarin or the presence of liver dysfunction), then FFP should be infused to restore normal coagulation. Endoscopy should not be delayed while waiting for normalization of the INR.^{14,15} For patients with GI hemorrhage who are being treated with a direct Factor Xa inhibitor (e.g., rivaroxaban), there are no FDA-approved antidotes. However, treatment with prothrombin complex concentrate (PCC) or activated Factor VIIa may be helpful.¹⁶ For patients with renal failure associated with possible uremic platelet dysfunction, desmopressin (DDAVP) should be administered to enhance platelet adhesion.^{17,18} For patients who are being treated with drugs, such as clopidogrel or aspirin (ASA), that inhibit the activation of platelets, platelet transfusion may be warranted. Platelet transfusion is also indicated for the treatment of thrombocytopenia (platelet count < 50,000/ μ L) in the setting of a GI hemorrhage. Treatment with tranexamic acid, a fibrinolysis inhibitor, should be considered in patients with a massive hemorrhage.¹⁹

Diagnosis and Treatment

These two steps need to be considered together because certain interventions, notably endoscopy and interventional radiology procedures, can serve both diagnostic and therapeutic goals.

Following the initial resuscitation, the diagnosis of the location of the hemorrhage becomes the priority. Initial assessment of the patient suspected of having UGI bleeding commences with a brief history and physical examination to establish potential sources of the bleeding and severity. Patients with a history of a previous GI hemorrhage episode are usually bleeding from the same location. The patient's medication history should be obtained, focusing on the use of NSAIDs or ASA, as well as anticoagulant drugs, such as warfarin or Factor Xa inhibitors. A nasogastric tube (NGT) should be placed early and lavage performed to help identify the source and possibly the severity of the hemorrhage.¹⁰ Even with blood in the rectum, NGT placement should be considered, as a UGI lesion could be the source of bleeding. If the NGT returns bilious material without any blood, then a distal source is more likely.²⁰

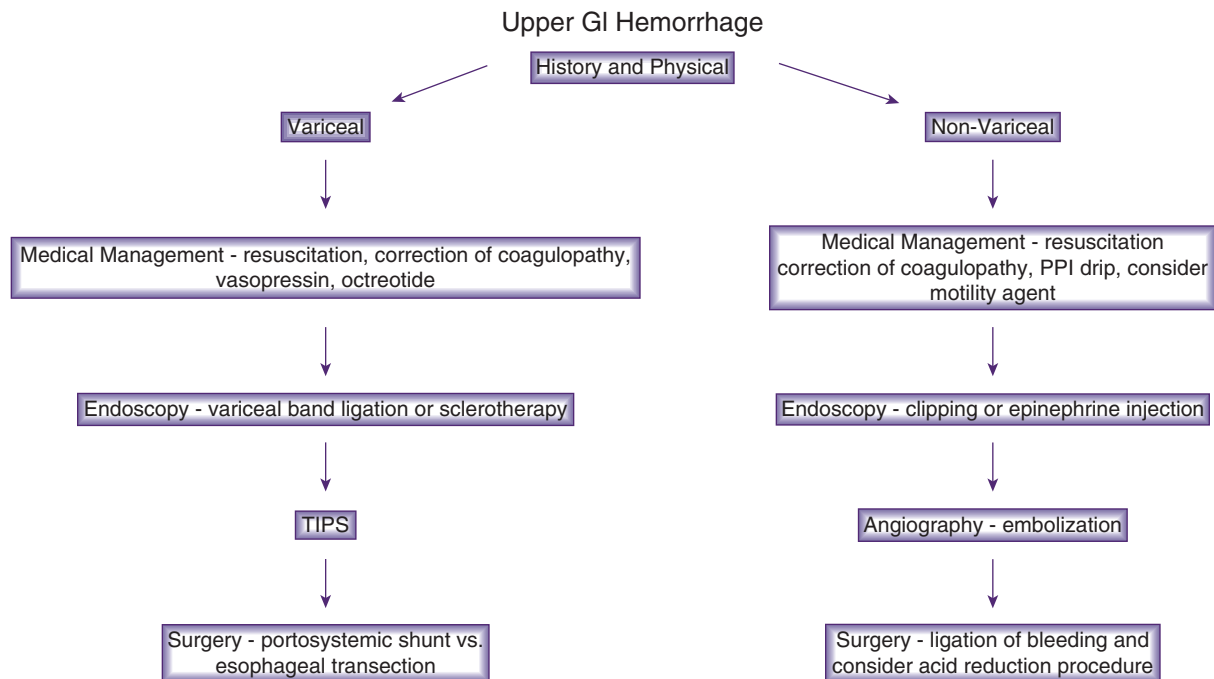

FIGURE 24-1 ■ Algorithm for Management of Upper GI Hemorrhage.

Fiber optic esophagogastroduodenoscopy is the next step in the diagnosis and treatment of patients with significant UGI bleeding. Endoscopy should ideally be performed when the patient is clinically stabilized and able to tolerate the procedure. Early endoscopy within 24 hours of admission can lower transfusion requirements, length of stay, and risk of mortality.²

If the patient experiences continued hemodynamic instability after the intervention, there is a risk that the patient may be experiencing rebleeding or a complication of endoscopy. Complications, such as perforation of the bowel, are surgical emergencies. Rebleeding occurs in about 20% of patients and increases the risk of mortality.^{21,22} With rebleeding, repeated endoscopy is typically warranted.

High-dose proton pump inhibitor (PPI) therapy to decrease gastric output should be initiated early when UGI bleeding is suspected. Treatment with a PPI can reduce the rate of rebleeding, decrease the length of hospital stay, and decrease the need for blood transfusion.²³ PPI therapy should be started before making a firm diagnosis, since the therapy can be stopped after endoscopy if it is no longer warranted. Pantoprazole should be administered as a bolus (80 mg IV) followed by a continuous infusion of 8 mg/h for 72 hours after significant bleeding has stopped, to lower the risk of rebleeding and mortality.^{24,25,26,27}

Prokinetic drug therapy prior to endoscopy has also been studied. The use of erythromycin or metoclopramide to stimulate gastric contractions and push the clot out of the stomach has been shown to clear the stomach of the clot burden and reduce the need for a repeat endoscopy to diagnose the source of the bleeding.^{28,29,30}

PUD

Patients presenting with bleeding secondary to PUD have a 90% rate of spontaneous resolution without intervention.^{24,21} Endoscopy should be performed and endoscopic treatment attempted to achieve hemostasis. A PPI should be infused and prokinetic therapy considered prior to endoscopy. Location of the bleeding is important and significant bleeding can occur from posterior ulceration of the proximal duodenum due to erosion into the gastroduodenal artery.

The Forrest classification system is used to identify ulcers with an increased likelihood of rebleeding. An actively bleeding vessel has a 90%-100% risk of rebleeding. A nonbleeding vessel has a 40%-50% risk of rebleeding. The presence of a visible clot carries a 20%-30% risk of rebleeding.

Endoscopic therapy should be attempted to stop the bleeding with coagulation, injection, and clipping as options. Endoscopy is successful at stopping acute bleeding in 90% of cases.³¹ Testing should be carried out to diagnose infection with *H. pylori* and if present, treated appropriately as likelihood of recurrent ulceration and bleeding is increased with persistence of *H. pylori* infection.³²

With continued bleeding or rebleeding, repeated endoscopic intervention should be attempted.²⁴ Repeat endoscopy was able to control bleeding in 73% of cases and was associated with less morbidity than surgical intervention even though mortality was similar. When endoscopy fails to control bleeding, angiography with embolization can be attempted prior to proceeding with surgical intervention. Embolization has a 90% success rate and is less invasive than surgical intervention. Superselective embolization is preferred as it carries a lower complication rate than embolization of larger vessels.³³ Superselective embolization may be associated with a higher risk of rebleeding. Early rebleeding rates are higher when angiography identifies significant active bleeding or is performed in patients with coagulopathy.³⁴ If a source of bleeding is identified during endoscopy and no extravasation is seen via angiography then relatively blind embolization can be performed with success.^{35,36} Common complications of embolization include bleeding from the site of arterial puncture and ischemia of the segment of bowel being embolized.

Surgical intervention is usually reserved for cases in which other interventions have failed to control the bleeding due to PUD. Patients requiring surgery are typically critically ill and other methods have failed and are therefore associated with a higher rate of mortality. Occasionally, a patient may present with separate bleeding and a perforated ulcer simultaneously. These are referred to as “kissing ulcers” and represent a unique surgical challenge. These patients are usually both hypovolemic from blood loss, septic from the perforated viscus, and are severely hemodynamically compromised.

Variceal Hemorrhage

Variceal disease secondary to cirrhosis and portal hypertension is another common cause of UGI bleeding. In patients with cirrhosis, varices form at a rate of 5%-15% per year and about 50% of people with cirrhosis have varices. One-third of patients with varices will develop a variceal hemorrhage.³⁷ The likelihood of developing a hemorrhage increases with the size of the varices and worsening portal hypertension.^{38,39} Particular attention needs to be paid to the correction of coagulopathy in patients with liver dysfunction. Mortality secondary to variceal hemorrhage is approximately 20%^{40,41} and rebleeding within the first six weeks occurs in 30%-40% of cases and is associated with an increased mortality rate.⁴²

Most bleeding varices are located in the lower third of the esophagus. Bleeding from gastric varices is often more severe than bleeding from esophageal varices and is more difficult to treat endoscopically.

When variceal bleeding is suspected, medical therapy should be initiated immediately and not delayed pending confirmation of a variceal source. The goal of pharmacologic therapy is to reduce portal venous blood flow and thus pressure. Useful medications include vasopressin, terlipressin, octreotide, and somatostatin. These agents are successful at controlling variceal hemorrhage in up to 80% of cases.⁴³ Administration of one or more of these agents prior to endoscopy can aid in visualization during the endoscopic intervention.^{41,44} Vasopressin promotes splanchnic arteriolar constriction, leading to decreased portal venous pressure. Terlipressin is a synthetic analog of vasopressin that has a longer duration of action but similar physiologic effects. Somatostatin and its longer acting analog, octreotide, inhibit the release of vasodilator hormones, such as glucagon and indirectly cause splanchnic vasoconstriction.⁴⁵ Somatostatin is administered as a 250 µg IV bolus followed by an infusion of 250 µg/h for up to 5 days to prevent rebleeding.⁴⁶ Octreotide has a longer half-life than somatostatin and is administered as a 100 µg IV bolus followed by infusion at 50-100 µg/h. Octreotide and somatostatin alone have not been proven to reduce mortality.^{47,48} Terlipressin is the only single agent that has been shown to reduce mortality however, it is not available in the United States.^{49,50} Vasoactive medications, in general, have been shown to decrease mortality, decrease hospital stay, improve hemostasis, and decrease blood transfusion requirements.⁵¹ Prophylactic broad spectrum antibiotics should be started early in patients with variceal hemorrhage as they have a risk of developing spontaneous bacterial peritonitis.^{52,53}

When variceal hemorrhage is suspected, endoscopy can be diagnostic and the therapeutic procedure of choice. Even when bleeding is short lived, endoscopy should be pursued as the rate of significant rebleeding is high. Options for endoscopic treatment include band ligation or sclerotherapy. Band ligation involves placing a small elastic band around the varices. Sclerotherapy involves injecting a sclerosant into the vein to cause thrombosis. Band ligation and sclerotherapy are both effective at stopping bleeding about 90% of the time, but the risk of rebleeding may be higher with sclerotherapy.⁵⁴

Another option for the management of bleeding from esophageal varices is the placement of a Sengstaken-Blakemore (SB) tube. The patient should first be intubated for airway protection. The tube is introduced through the mouth and into the stomach. Radiographic confirmation should be used to confirm that the gastric balloon is in the stomach before inflation, as inflation in the esophagus can cause rupture of the esophagus. The gastric balloon is then inflated with saline and placed on gentle traction to compress the gastroesophageal junction against the diaphragm and thereby tamponade hemorrhage. If bleeding stops, then the tube is secured without inflation of the esophageal balloon. If bleeding continues, the esophageal balloon is inflated until the bleeding stops. The pressure in the esophageal balloon cannot be allowed to exceed 45 mm Hg as doing so can lead to esophageal perforation. Inflation and traction are maintained for 24 hours. The SB tube is useful as a temporizing measure to control bleeding until other therapeutic options can be employed.

Transjugular intrahepatic portosystemic shunting (TIPS) should be considered in patients with refractory variceal bleeding despite medical

management. TIPS is performed via jugular cannulation. A catheter is advanced into a hepatic vein and then a needle is introduced through the hepatic parenchyma into the portal vein. This tract is then dilated and stented open to create a portosystemic shunt. Following TIPS, 90%-100% of patients will achieve hemostasis.^{42,55} Absolute contraindications to TIPS placement are heart failure, severe pulmonary hypertension, systemic infection, and severe tricuspid regurgitation. A relative contraindication is portal vein thrombosis. The patient should be monitored for the development of hepatic encephalopathy after the TIPS procedure.

Surgical interventions for the management of variceal hemorrhages, such as the creation of a side-to-side portocaval anastomosis or the Sigura procedure are rarely indicated or used. Mortality from these procedures approaches 50%.

Other Causes of UGI Bleeding

Stress ulceration can occur in critically ill patients, although this problem is relatively rare because of the routine use of drugs to inhibit gastric acid production in high-risk patients. When it occurs, GI hemorrhage secondary to stress ulceration is associated with a high mortality rate, since patients with this problem typically have significant comorbid conditions.

Mallory-Weiss tears are longitudinal disruptions of the mucosa of the distal esophagus or proximal stomach that result in submucosal bleeding.⁵⁶ These tears stop bleeding spontaneously in 90% of cases. The endoscopic intervention will control the bleeding in the remainder of cases.

Dieulafoy's lesion is a large anomalous submucosal artery that is most commonly located along the lesser curvature near the cardia of the stomach.^{57,58} Dieulafoy's lesion is responsible for about 2% of UGI bleeding episodes. Bleeding can be controlled endoscopically, with angiography and embolization, or surgically. Morbidity and mortality of bleeding due to Dieulafoy's lesion are high as patients with this problem typically have other comorbid conditions.⁵⁹

Other causes of significant UGI bleeding are hemobilia and aortoenteric fistula. Hemobilia should be part of the differential diagnosis when patients with UGI hemorrhage have a history of the recent hepatic instrumentation of any sort. Hemobilia is caused by hepatic arterial damage, leading to the formation of a fistula between the hepatic arterial tree and the biliary ductal system. Hemobilia usually presents with hematemesis. Endoscopy demonstrates blood coming from the bile duct. Hemobilia is most effectively treated with angiographic embolization of branches of the hepatic artery.

Aortoenteric fistula should be considered in patients with a history of abdominal aortic aneurysm repair. This problem commonly presents with a herald bleed and computed tomographic (CT) scanning of the abdomen usually shows signs of inflammation between the duodenum and the aorta. Aortoenteric fistula is a surgical emergency and patients suspected of having this diagnosis should be evaluated by a surgeon immediately.

LGI HEMORRHAGE

LGI bleeding is about half as common as UGI bleeding. The incidence of LGI bleeding is about 36/100,000 population. The mortality rate of acute LGI bleeding is 2%-4%.⁶⁰ Clinical factors predictive of severe colonic bleeding include anticoagulant use, comorbidities, tachycardia, hypotension, prior history of bleeding, and hospitalization for a different reason.⁶¹ Common causes of colonic bleeding include diverticulosis, cancer, and angiodysplasia. LGI bleeding presents with hematochezia. Melena can be a presenting sign if the rate of bleeding is relatively slow and the source is in the ascending colon. Even when hematochezia is the presenting sign, a UGI source of bleeding should still be ruled out with NGT lavage as UGI bleeding can present with hematochezia 10%-15% of the time.⁶⁰ Risk factors for complications include hemodynamic instability, advanced age, comorbidities, anticoagulation use, current hospitalization, and persistent signs of

Lower GI Hemorrhage

FIGURE 24-2 ■ Algorithm for Management of Lower GI Hemorrhage.

bleeding.^{62,63,64,65} In 80%-85% of patients, the bleeding will stop before the colonoscopy is performed.

Approach to the Patient

In general, the initial management of patients with significant LGI bleeding is similar to that already described above regarding the UGI hemorrhage (Fig. 24-2). Intravenous access and resuscitation should be initiated and coagulopathy (if present) corrected while diagnostic studies are being conducted to identify the source of the bleeding.

Localization

Colonoscopy should be the initial diagnostic study for locating the source of bleeding. However, performing a colonoscopy can be difficult in acutely bleeding patients. Bowel preparation is desirable but may not be possible if the patient is too unstable. Without bowel preparation, it is difficult to maneuver the scope all the way to the cecum and to locate the source of bleeding. In a randomized trial, urgent colonoscopy improved the localization of the source of bleeding compared with expectant management but did not reduce hospital stay, transfusion requirements, need for surgery, or mortality.⁶⁶

Localization also can be attempted with a radiolabeled red blood cell (RBC) scan. However, this approach is purely diagnostic and has no therapeutic potential. The overall rate of a positive scan is approximately 50%. However, 25% of tagged RBC scans suggest a location of bleeding that turns out to be incorrect. Angiography can localize the source of LGI bleeding. When a source is identified, the relevant vessel can be embolized at the time of the procedure. For patients with multiple repeat episodes of LGI bleeding with the inability to find the source of the bleeding, an infusion of heparin or tissue plasminogen activator (TPA) before and during angiography can be used to promote bleeding so it can be seen angiographically. If patients stabilize without the identification of a source of bleeding, they should be monitored for 24 to 48 hours before discharge. In unstable patients, if no LGI source of bleeding is found, UGI endoscopy should be performed as a UGI source is identified in up to 15% of patients.

Treatment

Colonoscopic interventions can control LGI bleeding in many cases. Embolization is another effective way of controlling hemorrhage. Embolization is feasible in 80% of patients with active bleeding

identified with angiography. When embolization is attempted, bleeding is successfully controlled in 97% of cases.⁶⁷ However, complications from embolization can be serious. There is a 20% risk of intestinal infarction, as well as risks of other complications, such as arterial thrombus formation or renal failure from the use of IV contrast.^{68,69}

In unstable patients with LGI bleeding and no acutely identifiable source, a subtotal colectomy may be necessary. This procedure is associated with significant morbidity and increased risk of complications. There is also the possibility that an occult lesion in the small intestine is responsible for the bleeding.

Diverticulosis is a common problem with more than 65% of people over the age of 80 having colonic diverticula. Diverticulae are predominantly located in the descending colon but bleeding is more common from diverticula in the ascending colon. Diverticular bleeding stops spontaneously in 75% of all cases and 99% of patients transfused with <4 units of PRBC, although there is a 38% risk of rebleeding.⁷⁰ Bleeding diverticula can usually be controlled with colonoscopic thermocoagulation, epinephrine injection, or hemoclip application.⁷¹

Postpolypectomy bleeding should be considered in patients with serious LGI bleeding after a polypectomy. This bleeding is usually from an arterial source. It can generally be treated with repeat colonoscopy and thermocoagulation, epinephrine injection, or hemoclipping.⁷²

Inflammatory bowel disease accounts for 1%-5% of all LGI bleeds.^{73,74,75,76} Severe bleeding is the reason for 10% of colectomies performed for ulcerative colitis.⁷⁷

Rectal bleeding is responsible for approximately 2% of LGI bleeding. It can be significant in patients with portal hypertension and bleeding hemorrhoids. Bleeding can be controlled with hemorrhoidal banding. Medical therapy to reduce portal venous pressure is important for long-term control in these patients.

Small Intestinal Bleeding

Between 1%-7% of patients with blood per rectum have a source located in the small intestine.^{78,79,80} The outcome for patients with a small bowel source of bleeding tends to be worse than for patients with GI hemorrhage from other sources. This is because bleeding from the small intestine continues without localization for a longer period. If there is continued significant bleeding without a visualized source on the upper or lower endoscopy, a small bowel source should be considered. Common reasons for small bowel bleeding are angiodysplasia, tumors, Crohns disease, or Dieulafoy's lesions.⁸¹ Angiodysplasia is common in the elderly with renal failure.⁸² Small bowel bleeding is intermittent in nature and is, therefore, difficult to identify with tagged RBC scan or angiography. Confirmatory diagnosis is often accomplished by capsule endoscopy, push enteroscopy, or double-balloon enteroscopy. Provocative angiography with heparin or TPA may be necessary to identify a source. Once the source of bleeding is identified, angiography with embolization or surgical resection is the treatment of choice.

KEY POINTS

1. Resuscitation, correction of coagulopathy, diagnosis, and treatment are the order of priorities when taking care of an acute GI bleed.
2. UGI bleeding is most commonly PUD or variceal in nature and patient history is key in making the diagnosis.
3. Medical management (PPI, octreotide) should be initiated when bleeding is suspected and not delayed until a diagnosis is made.
4. LGI bleeding is most commonly from diverticula and colonoscopy is the initial diagnostic and therapeutic procedure of choice.

■ DEFINITION AND DIAGNOSIS

While a normal peritoneal cavity contains only 25 mL of fluid, the peritoneum has the capacity to absorb 900 mL/day.¹ Ascites is the pathologic accumulation of peritoneal fluid, occurring most commonly in decompensated liver cirrhosis (85%), with malignancy, tuberculosis, heart failure, and pancreatitis accounting for the remainder.^{2,3} The International Club of Ascites classifies ascites severity, with fluid detectable only on imaging (<100 mL) as grade 1, moderate symmetric abdominal distention with up to 1 L of fluid as grade 2, and tense distention associated with a large volume of fluid as grade 3.⁴ Cirrhotic ascites can be uncomplicated or complicated, the latter involving concomitant development of spontaneous bacterial peritonitis (SBP), hepatorenal syndrome, or hepatic hydrothorax. Refractory ascites (5%-10% of cases) is persistent or rapidly recurring ascites despite maximal medical therapy.⁴

Symptoms of ascites include weight gain, abdominal pain, fullness, early satiety, and shortness of breath. History and physical exam looking for signs of liver disease or other underlying cause form the foundation of diagnostic evaluation. Detecting ascites on exam can prove difficult if <1500 mL is present. If flank dullness on percussion is not appreciated, there is a 90% chance no ascites is present.⁵ While CT will identify ascites, ultrasound is the preferred imaging modality. It is a highly sensitive, low-cost, non-radiation-producing method that simultaneously allows evaluation of the liver and hepatic vasculature.

Patients with new-onset ascites should undergo diagnostic paracentesis, with removal of 20 to 30 mL for evaluation of fluid color, turbidity, and total protein and for calculation of the serum-ascites albumin gradient (SAAG).^{6,7} An SAAG > 1.1 g/dL is 97% accurate in identifying ascites due to portal hypertension (Table 25-1).⁸ Infected ascites is a life-threatening complication, requiring timely assessment of the ascitic cell count and differential. A recent study of hospitalized patients with cirrhosis and SBP demonstrated a 3% increase in mortality for every hour that diagnostic paracentesis was delayed.⁹ Fluid can be sent for triglyceride levels if chylous ascites is suspected, amylase for pancreatitis, cytology for malignancy, or mycobacterium culture for tuberculosis.

■ PATHOPHYSIOLOGY

Portal hypertension from either increased hepatic resistance or increased portal blood flow is the key pathophysiologic event in the formation of ascites and is described in detail in Chapter 92. Normal portal venous pressure is <5 mm Hg. Once it is over 10 mm Hg, fluid from hepatic sinusoids and splanchnic capillaries overwhelms the peritoneal lymph drainage.^{3,10,11} However, increased pressure is only one aspect of the pathophysiology, as fluid dysregulation and development of ascites results from a complex interplay of hemodynamic and hormonal responses.^{7,12} In liver cirrhosis, hepatic sinusoidal congestion with progressive fibrotic transformation leads to endothelial cell dysfunction, causing nitric oxide-mediated vasodilation of splanchnic and peripheral arterial vascular beds. Initially, a hyperdynamic circulatory response compensates for the vasodilation to maintain adequate perfusion pressure. As vasodilation worsens and effective circulating volume decreases, however, compensatory activation of the sympathetic nervous and renin-angiotensin-aldosterone systems results in renal sodium and water retention, leading to fluid overload and hyponatremia (Fig. 25-1).¹²⁻¹⁸ This process is hastened when infection from bacterial translocation causes endotoxin release, compounding

vasodilation. Ultimately, tissue perfusion is compromised, leading to life-threatening organ dysfunction, the most salient being hepatorenal syndrome with a decreasing glomerular filtration rate and severe renal vasoconstriction, as detailed in Chapter 93. In contrast to the mechanisms in cirrhosis, ascites in infection and malignancy is due to inflammation and leakage of high-protein lymph.³

■ MANAGEMENT

Initial treatment of cirrhotic ascites is salt restriction (no more than 2000 mg/day) and oral diuretics to promote natriuresis. Although the aldosterone antagonist spironolactone can be used alone, addition of the loop diuretic furosemide, particularly in patients with a moderate to large volume of ascites, has proven efficacy and is recommended.^{19,20} Starting daily doses of 100 mg of spironolactone and 40 mg of furosemide achieve natriuresis without significant hypokalemia. Doses can be increased while maintaining the same ratio over 3 to 5 days to maximum daily doses of 400 mg of spironolactone and 160 mg of furosemide.^{6,21} Initial goals of diuretic therapy are weight loss of 0.5 kg/day (or up to 1 kg/day in edematous patients) and a measured 24-hour sodium excretion of 78 mmol/day.^{11,22} Side effects include intravascular volume depletion, renal insufficiency, and electrolyte abnormalities. If creatinine increases by more than 50% or more than 1.5 g/dL or if sodium falls by more than 10 mEq/L, therapy should be adjusted.²² Nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided, not only because of the risk of renal injury but also because they impede diuretic-mediated sodium excretion.²³ Along with standard diuretic therapy, midodrine at a dose of 7.5 mg orally three times a day can increase urine volume, urinary sodium excretion, and mean arterial pressure, resulting in significantly decreased mortality.²⁴

Paracentesis

Diuretics are started for initial control, but therapeutic paracentesis may also be indicated in settings of tense ascites to relieve abdominal pressure. The procedure is relatively safe when done under ultrasound guidance. Complications (<1%) include leakage of ascitic fluid, bleeding, infection, and bowel perforation.²⁵ Routine correction of thrombocytopenia or prolongation in the prothrombin time is not recommended, as paracentesis has been performed safely in patients with platelets < 50,000/uL and INR > 2. In a retrospective study of 4729 procedures, the incidence of significant bleeding was relatively low (0.19%) despite coagulopathy in many patients.²⁶ The only real contraindication to paracentesis is disseminated intravascular coagulopathy.

Following removal of a large volume, paracentesis-induced circulatory dysfunction can result from effective hypovolemia with activation of the renin-angiotensin system, resulting in hyponatremia and renal impairment. When fluid removal exceeds 5 L, intravenous replacement of albumin is recommended (8 g/L of ascites removed), which is supported by data demonstrating improved survival.²⁷ While large-volume paracentesis is time consuming and costly, benefits include improved patient comfort, shortened hospitalization, preserved hemodynamics, and a decreased risk of SBP and hepatic encephalopathy.²⁸

■ PROGNOSIS AND COMPLICATIONS

Ascites signifies progression from compensated to decompensated liver failure and carries a 20% 1-year mortality.²⁹ Within the first

TABLE 25-1

Causes of Ascites in the Normal or Diseased Peritoneum by Serum-to-Ascites Albumin Gradient (SAAG)

NORMAL PERITONEUM

PORTAL HYPERTENSION (SAAG > 1.1 g/dL)

Hepatic congestion
Congestive heart failure
Constrictive pericarditis
Tricuspid insufficiency
Budd-Chiari syndrome

HYPOALBUMINEMIA (SAAG < 1.1 g/dL)

Nephrotic syndrome
Protein-losing enteropathy
Severe malnutrition with anasarca

LIVER DISEASE

Cirrhosis
Alcoholic hepatitis
Fulminant hepatic failure
Massive hepatic metastases

MISCELLANEOUS CONDITIONS (SAAG < 1.1 g/dL)

Chylous ascites
Pancreatic ascites
Bile ascites
Nephrogenic ascites
Urine ascites
Ovarian disease

DISEASED PERITONEUM (SAAG < 1.1 g/dL)

INFECTIONS

Bacterial peritonitis
Tuberculous peritonitis
Fungal peritonitis
HIV-associated peritonitis

OTHER RARE CONDITIONS

Familial Mediterranean fever
Vasculitis
Granulomatous peritonitis
Eosinophilic peritonitis

MALIGNANT CONDITIONS

Peritoneal carcinomatosis
Primary mesothelioma
Pseudomyxoma peritonei
Hepatocellular carcinoma

decade of diagnosis, 50% of patients with cirrhosis will develop ascites.³⁰ Once complications such as refractory ascites or hepatorenal syndrome develop, yearly mortality increases to 75%.^{31,32} Ascites features in a validated scoring system for liver failure, serving as one of five components of the Child-Turcotte-Pugh (CTP) score that also factors in encephalopathy, albumin, INR, and total bilirubin to predict mortality.³³ Given the poor prognosis, once ascites develops, patients should begin evaluation for liver transplantation.

Spontaneous Bacterial Peritonitis

SBP occurs in 30% of patients with ascites, carries a 20% mortality rate, and is defined by³⁴:

1. Positive bacterial culture (single organism)
2. Ascitic fluid polymorphonuclear cell count $\geq 250/\text{mm}^3$
3. Absence of surgically treatable source of infection

SBP arises from translocation of intestinal bacteria, predominantly *Escherichia coli* and *Klebsiella*.³⁵ Common symptoms include fever, abdominal pain, nausea and vomiting, increasing encephalopathy, and decreased renal function. Prompt diagnostic paracentesis is indicated, with ascitic fluid sent for cell count, total protein, glucose, amylase, lactate dehydrogenase, Gram stain, and anaerobic and aerobic cultures. Cultures of ascitic fluid should be inoculated in blood culture bottles at the bedside to maximize chances of identifying a causative organism.^{7,21} Patients with a low ascitic protein content ($<1.5 \text{ g/L}$) are particularly at risk of developing SBP.³⁶ Treatment should start as soon as infection is suspected with a third-generation cephalosporin, such as ceftriaxone or cefotaxime, for a 5- to 7-day course.^{6,21}

SBP should be differentiated from secondary bacterial peritonitis due to abscess or perforated viscus, as treatment is substantially different. Secondary bacterial peritonitis should be suspected if ascitic fluid analysis has a glucose $<50 \text{ mg/dL}$, elevated lactate dehydrogenase, or polymicrobial culture results.³⁷ Further workup includes upright plain films, CT with water-soluble contrast, and surgery consultation.

TABLE 25-2

Management of Refractory Ascites

Definitions

Ascites that is not eliminated even with maximum diuretic therapy
Ascites that is not eliminated because maximum dosages of diuretics cannot be attained, given the development of diuretic-induced complications

Recommended therapy

Total paracentesis + IV albumin (6-8 g/L of ascites removed)
If $<5 \text{ L}$ of ascites is removed, a synthetic plasma volume expander may be used instead of albumin.
Continue with salt restriction and diuretic therapy as tolerated.

Alternative therapy

TIPS for patients who require frequent paracenteses (every 1-2 weeks) and whose CTP score is ≤ 11
Peritoneovenous shunt for patients who are not candidates for TIPS or transplant

CTP, Child-Turcotte-Pugh; IV, intravenous; TIPS, transjugular intrahepatic portosystemic shunt. Data from Garcia-Tsao G, Lim JK; Members of the Veterans Affairs Hepatitis C Resource Center Program. Management and treatment of patients with cirrhosis and portal hypertension: recommendations from the Department of Veterans Affairs Hepatitis C Resource Center Program and the National Hepatitis C Program. *Am J Gastroenterol*. 2009;104:1802-1829.

After an initial SBP event, the chance of a repeat infection is 70%.³⁸ A meta-analysis of eight studies of 647 patients investigating antibiotic prophylaxis to prevent recurrent SBP demonstrated an overall mortality of 16% in the antibiotic group versus 25% for the control. Statistically significant improvements were seen in rates of re-infection as well as a 3-month survival benefit.³⁹ Oral prophylaxis with norfloxacin or trimethoprim/sulfamethoxazole is recommended for patients following one SBP episode and, for those with active gastrointestinal bleeding, a low-protein ascitic fluid ($<1.5 \text{ g/dL}$), impaired renal function ($\text{Cr} \geq 1.2$), or liver failure (CTP score ≥ 9 and bilirubin ≥ 3).⁶

Refractory Ascites

Refractory ascites is diagnosed when maximal medical management for at least 1 week or repeated large volume paracenteses within 4 weeks are insufficient to remove ascites.¹⁵ Diuretic failure results from resistance to or complications from therapy, including renal impairment or electrolyte perturbations (hypo- or hyperkalemia, hyponatremia). Refractory ascites carries a mortality of 21% at 6 months and 70% at 2 years, so expedited evaluation for liver transplantation is indicated.⁴⁰ Treatment consists of serial therapeutic paracentesis, transjugular intrahepatic portosystemic shunt (TIPS), or liver transplantation (Table 25-2).

TIPS involves percutaneous placement of an expanding metal stent within an artificially created channel that diverts portal blood flow into the hepatic veins, thus decreasing portal hypertension and ascites. Consideration for TIPS occurs once patients require more than two large volume paracentesis in a month. Complications include stent occlusion, worsened liver failure, heart failure, infection, renal failure, and increased hepatic encephalopathy. In the most recent meta-analysis of TIPS versus repeated paracentesis aggregating six randomized controlled trials with a total of 390 patients, TIPS was shown to significantly improve liver transplant free survival ($\text{HR} = 0.61$, 96% CI 0.46-0.82, $P < 0.001$).^{40a} This is different from a previous Cochrane review of five randomized control trials dating from 1996 to 2004 comparing 162 patients who showed no difference in 30-day or 2-year mortality. However, patients who underwent TIPS showed a significant increase in hepatic encephalopathy (OR 2.24, 95% CI 1.39, $P < 0.01$).⁴¹ Selection of patients for TIPS is key. It is not recommended if bilirubin is $>5 \text{ mg/dL}$, age > 70 years old, model for end-stage liver disease score > 18 , or CTP score > 11 .^{42,43}

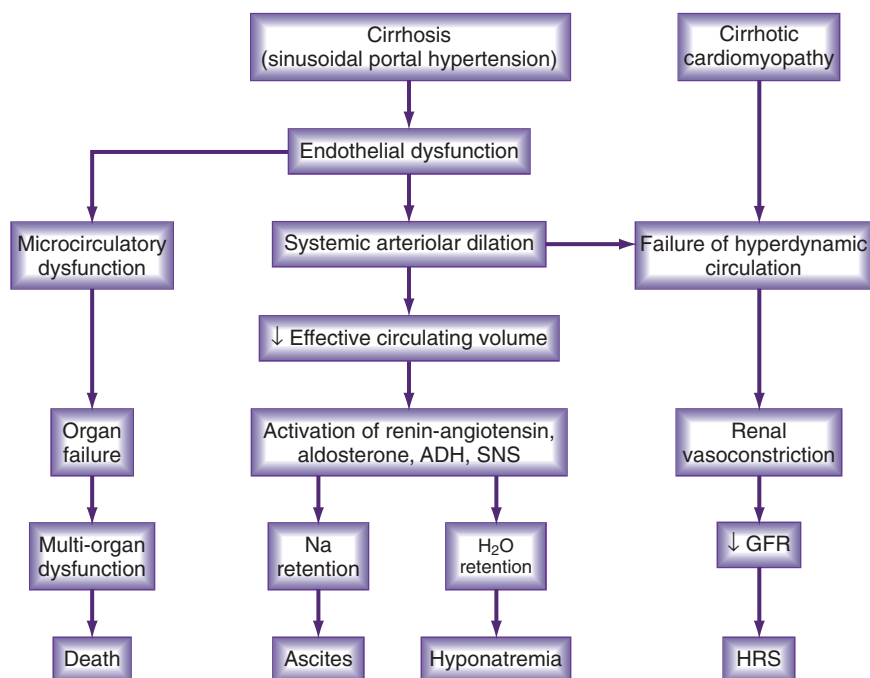

FIGURE 25-1 ■ Pathophysiology of cirrhosis and ascites. Cirrhosis is associated with splanchnic arterial vasodilation, leading to a decrease in effective circulating volume and a hyperdynamic circulation. The decrease in effective circulating volume causes the activation of renal sodium and water retentive pathways (e.g., RAAS, renal SNS, and ADH). Resulting sodium and water retention leads to ascites due to the spillage of excess sodium and water from hepatic lymph into the peritoneal cavity. As the disease progresses, a progressive decrease in effective circulating volume develops, causing severe renal vasoconstriction and a decrease in glomerular filtration rate. The onset of cirrhotic cardiomyopathy accentuates this problem and tips the patient over into hepatorenal syndrome. The accompanying circulatory disturbance leads to organ failure and death. Sepsis is frequently associated with this process. ADH, antidiuretic hormone; RAAS, renin-angiotensin system; SNS, sympathetic nervous system. (From Salerno F, Camma C, Enea M, Rossle M, Wong F. Transjugular intrahepatic portosystemic shunt for refractory ascites: a meta-analysis of individual patient data. *Gastroenterology*. 2007;133:825-834.)

KEY POINTS

1. Ascites is most commonly due to liver disease and has a 20% yearly mortality.
2. Diagnostic paracentesis should be performed in all patients with new ascites to differentiate between ascites secondary to portal hypertension (SAAG > 1.1 g/dL) from other conditions.
3. Medical management includes sodium restriction and oral diuretics, usually starting with spironolactone 100 mg and furosemide 40 mg daily.
4. SBP is a life-threatening complication, and treatment should begin promptly with a third-generation cephalosporin as soon as infection is suspected.
5. Treatment options for refractory ascites include serial paracentesis or TIPS, but expedited evaluation for liver transplantation should also begin for appropriate candidates.

ANNOTATED REFERENCES

Garcia-Tsao G, Lim JK, Members of Veterans Affairs Hepatitis C Resource Center Program. Management and treatment of patients with cirrhosis and portal hypertension: recommendations from the Department of Veterans Affairs Hepatitis C Resource Center Program and the National Hepatitis C Program. *Am J Gastroenterol*. 2009;104:1802-1829.

This comprehensive review provides evidence-based recommendations for management of the patient with either compensated or decompensated cirrhosis, including management of ascites, refractory ascites, SBP, and other complications, including hepatorenal syndrome.

Bai M, Qi X-S, Yang Z-P, Yang M, Fan D-M, Han G-H. TIPS improves liver transplantations-free survival in cirrhotic patients with refractory ascites: an updated meta-analysis. *World Journal of Gastroenterology*. 2014;20(10):2704-2714.

This updated meta-analysis of six randomized controlled trials with 390 patients showed a significant improvement of transplant-free survival of cirrhotic patients with refractory ascites, decreased ascites recurrence, and improved hepatorenal syndrome despite a significantly higher number of hepatic encephalopathy episodes in the TIPS group.

Wong CL, Holroyd-Leduc J, Thorpe KE, Straus SE. Does this patient have bacterial peritonitis or portal hypertension? How do I perform a paracentesis and analyze the results? *JAMA*. 2008;299:1166-1178.

This publication includes a systematic review of nine randomized controlled trials (n = 806 procedures) that examined the use of plasma expanders for therapeutic paracentesis. No significant differences

were identified between therapeutic paracentesis with and without volume expansion with albumin, nor with nonalbumin plasma expanders compared with albumin in terms of hyponatremia, renal impairment, encephalopathy, or death. However, these studies did not specifically examine prevention of paracentesis-induced circulatory dysfunction (defined by an increase in plasma renin activity or aldosterone concentration), and some studies determined that albumin prevented this condition more effectively than synthetic plasma expanders.

Saab S, Hernandez JC, Chi AC, Tong MJ. Oral antibiotic prophylaxis reduces spontaneous bacterial peritonitis occurrence and improves short-term survival in cirrhosis: a meta-analysis. *Am J Gastroenterol*. 2009;104:993-1001.

This meta-analysis of eight prospective clinical trials with a total of 647 patients randomized to oral antibiotic prophylaxis for SBP compared with placebo or no intervention documented an overall mortality benefit (RR = 0.65; 95% CI 0.48-0.88) for antibiotic treatment groups. The overall mortality rate was 16% for treated patients and 25% for the control cohort. Groups treated with prophylactic antibiotics also demonstrated a lower incidence of all infections (including SBP) of 6.2% compared with the control group rate of 22.2% (RR = 0.32; 95% CI 0.20-0.51).

Acute abdominal pain in the critically ill has a differential that is expansive and a diagnosis that can be difficult. The differential encompasses the same disease states as for noncritically ill patients but additionally includes causes specific to special cohorts including those who have been hospitalized for prolonged periods, the elderly, the immunosuppressed, the injured, and postsurgical patients. Because of this diversity, the diagnosis and management of acute abdominal pain require critical care practitioners to have a thorough understanding of the mechanisms and pathophysiology of different causes of acute abdominal pain and the ability to recognize more than classic patterns and presentations. Understanding abdominal pain begins with understanding the neurologic reception of pain in the abdomen, which is dependent on both mechanical and chemical stimuli. Pain elicited by mechanical stimuli is primarily driven by the stretch of visceral receptors located on serosal surfaces, in the mesentery, and between the muscularis mucosa and submucosa of hollow visceral organs. Additionally, pain elicited by chemical stimuli is primarily driven by mucosal reception of substances that include substance P, bradykinin, serotonin, histamine, and prostaglandin in response to inflammatory or ischemic signals.¹⁻³ The localization of pain is dependent on the type, distribution, and number of visceral nociceptors; therefore, the processing of these signals varies between individuals and pathologies.⁴ Because of these complexities, pain that is perceived in the abdomen may actually arise from other nonvisceral locations including myocardial ischemia, pneumonia, and herpes zoster, among others.

INITIAL APPROACH

Underlying disease or chemically induced depression in consciousness level in intensive care unit (ICU) patients inhibits their ability to communicate and the physician's ability to perform an adequate physical exam. At times, patients are so critically ill that they may not be able to travel for adjunct studies, further compromising traditional diagnostics.

Patient History

Despite limitations, trying to glean an adequate history, including the presence of symptoms associated with pain such as fever, chills, nausea, vomiting, diarrhea, constipation, obstipation, and bloating, can be critical. Events before and during the patient's hospitalization are important to the history, including arrhythmic events, hypotensive episodes, and medications administered (including vasopressors and antibiotics). The events before the patient's hospitalization hold the same importance given that the nidus for their abdominal pathology may have existed before their critical illness.

Physical Exam

The physical exam is centered on the standard abdominal exam but must additionally include examination of all tubes (nasal- and orogastric, rectal, urinary drainage catheters, and surgical drains) for both quantity and quality of output. Assessment of all surgical scars and their stage of healing is critical. Additionally, an assessment of the patient's vital signs and any hemodynamic-altering medications remains important.

Diagnostic Adjuncts

Laboratory adjuncts include complete blood counts with leukocyte differentials, comprehensive metabolic panels including liver function tests with conjugated bilirubin, coagulation studies, arterial or venous blood gases, and lactic acid measurements. If concern for infection exists, complete infectious workups, including chest plain radiography to evaluate for intrathoracic processes, urine analysis and culture, blood cultures from central and peripheral lines, stool cultures, and *Clostridium difficile* toxin assays, should be considered. Radiographic adjuncts include plain films, ultrasound to evaluate for biliary tract and renal disease, and computed tomography (CT) to evaluate for other intraabdominal sources of pain.

This chapter will focus on the broad differentials based on location of abdominal pain with spotlights on certain diagnoses that have noteworthy importance in critically ill patients.

DIFFERENTIAL DIAGNOSES BASED ON LOCATION

The differential diagnosis of abdominal pain in critically ill patients is expansive (Fig. 26-1). Upper abdominal pain can have cardiac and respiratory causes, whereas lower abdominal pain can have urologic and gynecologic causes.

Upper Abdominal Pain

Upper abdominal pain may have an origin in the upper digestive tract, including gastritis and peptic ulcer pathology. Alternatively, pain may come from the biliary tract, including calculous and acalculous cholecystitis, cholangitis, pancreatitis, splenic infarction, or abscess. Organ systems and disease processes outside the abdomen, including ischemic heart disease and pneumonia, should always be entertained as causes of upper abdominal pain in the appropriate patient.

Of particular importance in critically ill patients are biliary and gastric or peptic sources of abdominal pain. Right upper quadrant and epigastric pain coupled with fever, leukocytosis, and alterations in liver functions tests can distinguish biliary pathologies. Ultrasonography is the most sensitive imaging modality. In addition, the use of ultrasound in the ICU is practical and can distinguish among different types of biliary diseases.

Acalculous cholecystitis is associated with prolonged enteral fasting states. The mortality of acalculous cholecystitis is high; therefore, prompt diagnosis and treatment are critical.^{5,6} For all cholecystitis, drainage via cholecystostomy tube is a lifesaving intervention in someone critically ill and unfit for surgery.⁵

Gastric and peptic sources of abdominal pain can occur secondary to physiologic stress-related mucosal damage of the gastroduodenum. One primary driver of this condition is prolonged mechanical ventilation. The presenting symptoms of gastritis and peptic ulceration can range from painless gastrointestinal bleeding to epigastric pain to peritonitis due to perforation. If upper abdominal pain is thought to be secondary to gastroduodenal ulceration, upper endoscopy is diagnostic. Suitable treatment includes the administration of proton pump inhibitors and removal of offending agents, including nonsteroidal antiinflammatory medications. If the patient's acute abdominal pain is due to perforated gastroduodenal ulcer, surgical repair is required.

| Upper | Lower | Generalized |
|---|--|--|
| Gastritis Peptic ulcer disease Biliary tract disease Pancreatitis Hepatitis Pulmonary embolism Pneumonia Myocardial infarction | Gastroenteritis Ischemic or infectious colitis Acute mesenteric ischemia Appendicitis Diverticulitis Inflammatory bowel disease Sigmoid/cecal volvulus Ovarian cyst/torsion Testicular torsion Cystitis/pyelonephritis Ectopic pregnancy Prostatitis Salpingitis | Perforated viscus Ruptured aortic aneurysm Nephrolithiasis Intraabdominal abscess |

FIGURE 26-1 ■ Differential diagnosis of acute abdominal pain by location in critically ill patients.

New data highlighting an increased incidence of infectious complications including hospital-acquired pneumonia and *C. difficile* enteritis with the administration of stress ulcer prophylaxis has led to the questioning of the routine use of stress-ulcer prophylaxis.⁷ Modern meta-analyses suggest that critically ill patients who are enterally fed do not require stress-ulcer prophylaxis.

Similar to biliary sources of abdominal pain, the acute inflammation of pancreatitis can produce characteristic upper abdominal pain in the epigastrium with radiation to the back. In acute pancreatitis, approximately 15% of patients can develop sepsis and multiorgan failure with an overall mortality of 13%.^{8,9} Laboratory findings include elevated serum lipase and metabolic abnormalities including hemoconcentration, hypocalcemia, and hyperglycemia. CT findings may include focal or diffuse enlargement of the pancreas, with peripancreatic fluid and fat stranding and abnormal enhancement in areas of necrosis. When CT is performed 3 or more days after the onset of pain, it can reliably predict the severity of disease, the extent of necrosis, and the presence of local complications.¹⁰ Management of acute pancreatitis has changed over the years in regard to fluid resuscitation, prophylactic antibiotics, and surgical débridement.¹¹ Recent studies have shown that less aggressive resuscitative measures have led to improved outcomes.¹²⁻¹⁴ The incidence of abdominal compartment syndrome in patients with acute pancreatitis is as high as 85%;¹⁵ however, more restrictive resuscitative measures are found to be associated with a lower incidence.¹⁶

Two large randomized controlled trials confirmed that antibiotics should be given only with demonstrated infected pancreatic necrosis.^{17,18} The surgical treatment of pancreatic necrosis has also evolved, and less invasive approaches are associated with better outcomes.¹⁹ Algorithms now include first-line percutaneous drainage procedures followed by endoscopic and minimally invasive surgeries and avoidance of early surgery if possible.^{20,21} Finally, evidence supports early (within 24 hours) enteral nutrition in acute pancreatitis to prevent bacterial translocation. Nasogastric feeds may be comparable to nasojejunal feeds in efficacy and complications.²²⁻²⁴

Lower Abdominal Pain

Lower abdominal pain usually has an origin in the lower digestive tract and can be due to colitis (infectious, ischemic), acute colonic pseudo-obstruction, sigmoid or cecal volvulus, diverticulitis, or appendicitis. Additionally, one must entertain abdominal or pelvic sepsis due to intraabdominal abscess in certain populations of patients, including those who have had previous abdominal surgery or have a known perforation of a hollow viscus organ (including perforated diverticulitis and appendicitis). Neutropenic patients are at risk of developing neutropenic enterocolitis, which can manifest with lower abdominal pain, fevers, leukocytosis, diarrhea, and imaging consistent with colitis.

Organ systems outside the abdomen, including gynecologic and urologic (urinary tract infection, kidney stones, bladder distention, pelvic inflammatory disease, adnexal pathology, endometriosis, and pregnancy), should be taken into consideration.

Abdominal pain from infectious or ischemic colitis can be from local inflammation, necrosis, or perforation. Lower abdominal pain coupled with fever, leukocytosis, acidosis, elevated lactate and bloody or nonbloody diarrhea should prompt immediate evaluation. Ischemic colitis may be caused by vascular occlusion or may be nonocclusive. Acute arterial occlusion (embolic or thrombotic), venous thrombosis, and nonocclusive hypoperfusion can all lead to intestinal ischemia. Certain patient populations, particularly those who have undergone ligation of the inferior mesenteric artery in aortic repairs, are at increased risk, and the presence of postoperative diarrhea, abdominal pain, or acidosis should prompt immediate colonoscopic evaluation. Although there are multiple causes of ischemic colitis, all lead to mucosal injury.²⁵

Nongangrenous colitis is the most common colonic ischemia and is usually seen in “watershed” areas including the splenic flexure and rectosigmoid junction of the colon. This condition can be treated with resuscitation and has a low mortality rate. However, gangrenous colitis requires early recognition and surgical treatment and has a mortality rate between 50% and 75% for those surgically treated and 100% for those who are too ill to undergo surgical intervention.²⁶ CT scan findings are nonspecific; the gold standard for diagnosis is colonoscopic evaluation. Broad-spectrum antibiotics should be started in cases where ischemia is suspected.²⁷ If ischemia is secondary to mesenteric venous thrombosis or has an embolic source, anticoagulation is then indicated. Life-saving surgery is reserved for full thickness ischemia or perforation, which is needed in approximately 20% of cases.²⁸

Critically ill patients are at an increased risk of infectious causes of colitis as well. The gastrointestinal tract is colonized with pathogenic organisms, the most intrusive of which is *C. difficile*, a spore-forming anaerobic and gram-positive bacillus bacterium. This bacterium colonizes healthy individuals but can become an invasive organism leading to cytotoxic bowel inflammation, pseudomembrane formation, toxic megacolon, and perforation in patients exposed to antibiotic treatment; it has a high morbidity and mortality rate in hospitalized patients. Lower abdominal pain, fever, bloody or nonbloody diarrhea, and leukocytosis should prompt evaluation for *C. difficile* infection in any such patient who has had exposure to antibiotics. An unexplained leukocytosis in a critically ill patient without other symptoms may be *C. difficile* infection.²⁹ Diagnosis is made with identification of *C. difficile* toxins or toxigenic *C. difficile* in stool.³⁰ Additionally, *C. difficile* can be diagnosed by colonoscopic and histopathologic findings of pseudomembranes, which are virtually pathognomonic. Fulminant colitis can progress to toxic megacolon and perforation. Additionally,

manifestations of symptoms of ileus without diarrhea can be present because of a dilated and nonfunctional colon.^{31,32} Toxic megacolon is a clinical diagnosis based on colonic distention up to >7 cm at the greatest diameter with associated severe shock. Prompt surgical evaluation and intervention are essential.

Finally, acute colonic pseudo-obstruction (Ogilvie's syndrome) characteristically has significant dilation of the cecum and right colon without any anatomic obstruction and is associated with underlying disease in 95% of patients; it has a strong association with opiate administration.³³ Lower abdominal pain coupled with constipation, distention, nausea, vomiting, and paradoxical diarrhea are common. Most patients have metabolic derangements that may be reflected in electrolyte abnormalities.³³ Plain supine imaging reveals a distended colon (most often right-sided), and CT confirms the diagnosis by excluding evidence of mechanical obstruction or toxic megacolon due to colitis. Treatment includes relieving distention and discomfort and avoiding complications such as perforation. Treat the underlying cause, correct electrolyte abnormalities, provide gastric and rectal decompression, and avoid opiates, sedatives, and anticholinergics. The anticholinesterase inhibitor neostigmine may be effective for colonic decompression but requires cardiac monitoring and should be used with caution in patients with asthma or cardiac abnormalities and the elderly.³⁴ Colonoscopic decompression can be attempted when supportive measures fail.

Generalized Abdominal Pain

Generalized abdominal pain may represent severe and life-threatening diseases such as mesenteric ischemia, peritonitis, intestinal obstruc-

tion, ruptured abdominal aortic aneurysm, or an alternatively benign disease, including constipation. Peritonitis is nonspecific inflammation of the peritoneum that has multiple causes. Pain is usually in the region of the source but becomes generalized as the inflammation progresses. Other findings of peritoneal inflammation include fever, tachycardia, hypotension, significant tenderness on exam with rebound tenderness, involuntary guarding, and rigidity due to the activation of the afferent visceral and cutaneous pain receptors. Laboratory evaluations including complete blood count, comprehensive metabolic panel, and lactate, as well as imaging with upright plain abdominal films to evaluate for intraperitoneal air and CT of the abdomen are cornerstones of identifying the cause of peritonitis. Patients with generalized peritonitis often require surgical exploration without imaging in many cases.

Intestinal obstruction may present with acute crampy diffuse abdominal pain coupled with nausea and vomiting, obstipation, distention, and tenderness on exam. Obstruction can be partial or complete and can involve the small or large bowel. Obtaining an adequate history of previous surgeries and colonoscopies is important. Additional findings including fever, tachycardia, leukocytosis, and lactic acidosis are concerning for intestinal ischemia due to obstruction. Plain imaging will demonstrate air-fluid levels and dilated bowel (large or small). CT with oral contrast can often identify a transition point or other causes of obstruction like volvulus or intussusception. Decreased intestinal wall enhancement on CT, peritoneal signs, and leukocytosis are predictive of intestinal ischemia in patients with small bowel obstructions.³⁵ Nonoperative management may be appropriate with nasogastric decompression and bowel rest. However, in bowel obstructions that do not resolve or have signs of ischemia present, surgical management is imperative.

Ileus is defined as the disruption of normal coordinated propulsive motor activity of the gastrointestinal (GI) tract due to a nonmechanical cause.¹ Ileus most frequently occurs in the postoperative setting and may be viewed as a normal physiologic response to abdominal surgery.² However, when ileus is prolonged, it must be differentiated from mechanical bowel obstruction or other postoperative complications.

■ PATHOPHYSIOLOGY

Physiologic bowel motility is a complex process that results from the interaction of various neural networks and neurohormonal mediators. During the fasting state, the coordinated contractions of the GI tract are referred to as *migrating motor complexes* (MMC). The contractions occur in three phases: the resting phase, intermittent contractions of moderate amplitude, and high-pressure waves. When a food bolus is introduced into the intestine, the MMCs terminate, and the digested food, or chyme, is propelled through the GI tract via coordinated contractions (peristalsis) of the smooth muscle layers in the intestinal wall. This process is regulated primarily by the enteric nervous system (ENS), which is comprised of myenteric and submucosal sensory and motor nerve plexi and the interstitial cells of Cajal. The ENS transmits sensory information from the intestinal wall to the central nervous system (CNS) via a network of visceral sensory afferents in the vagus, splanchnic, and pelvic nerves. The ENS also connects the visceral motor efferents in these same nerves with the intestinal smooth muscle cells. The ENS and intestinal smooth muscle activity are inhibited by sympathetic signaling and stimulated by parasympathetic cholinergic signaling. Alternatively, the ENS can function independently of CNS control via the autonomic nervous system through secreted mediators that include substance P, vasoactive intestinal peptide, and nitric oxide.

Ileus can develop when physiologic neural signaling and neurohormonal networks are disrupted. Ileus can result from the presence of inhibitory neuroenteric signaling through increased sympathetic activity, inflammation of surrounding organs or the bowel wall itself, paracrine and endocrine activity of inhibitory gastrointestinal peptides or endogenous opioids, and the use of exogenous opioids for analgesia.³

Ileus is common following abdominal operations. Traditionally, it has been taught that small-bowel motility returns within the first 24 hours after the procedure, gastric motility returns within 24 to 48 hours, and colonic motility within 48 to 72 hours.⁴ However, recent studies demonstrate that the duration of postoperative intestinal dysmotility may be shorter than previously thought; gastric and small intestinal motility return within hours of surgery, and colonic activity may return by postoperative day 2 or 3.⁵⁻⁷ When the expected period of time extends beyond what is viewed as acceptable in common practice, which is 5 days for open abdominal operations and 3 days for laparoscopic procedures, the patient has a pathologic postoperative ileus and a cause for ileus should be sought.⁸

■ CLINICAL FEATURES

Symptoms of ileus can include abdominal distention, bloating, diffuse abdominal pain, nausea, vomiting, inability to tolerate an oral diet, and inability to pass flatus or stool. Physical examination generally reveals

abdominal distention, tympany, and decreased or absent bowel sounds. There are no diagnostic laboratory tests for ileus, but workup may reveal associated pathologic conditions such as electrolyte abnormalities, or leukocytosis secondary to an intraabdominal infection.

Distinguishing ileus from a mechanical bowel obstruction is often difficult as these conditions share many of the same signs and symptoms. For this reason, imaging studies may be necessary to make the correct diagnosis. Plain abdominal films are often the first imaging modality obtained and will show dilated loops of bowel with air in the colon and rectum without a transition zone to suggest obstruction (Fig. 27-1). If plain films are not helpful or there is suspicion of a secondary cause of ileus (such as an intraabdominal abscess), abdominal CT should be obtained (Fig. 27-2). CT has a sensitivity and specificity of 90% to 100% in distinguishing ileus from complete mechanical bowel obstruction.⁹

■ TREATMENT

There are no data to support specific therapy for ileus, and treatment is largely supportive care. The first step is identification and remediation of any inciting factors, which may include medications, electrolyte abnormalities, or other underlying intraabdominal processes. Medications known to be associated with bowel dysmotility include narcotics, phenothiazines, diltiazem, anticholinergics, and clozapine. These medications should be discontinued if possible, and opioids should be used sparingly for pain control. Electrolyte abnormalities including hypokalemia, hyponatremia, hypo- and hypermagnesemia, and hypo- and hypercalcemia have all been shown to contribute to the development of ileus.

While awaiting recovery of bowel function, patients should be made nil per os (NPO) and given adequate intravenous fluids to maintain normovolemia. For patients with moderate to severe abdominal distention, nausea, or vomiting, a nasogastric (NG) tube should be placed for decompression. In the absence of these findings, NG insertion is not recommended, as it does not speed recovery from ileus and may in fact contribute to other complications including atelectasis and pneumonia.¹⁰

Studies on the administration of pharmacologic promotility agents for resolution of ileus have been disappointing, and there are no data to support use of metoclopramide or erythromycin.¹¹ More recently, the peripherally acting mu-opioid receptor antagonists, alvimopan and methylnaltrexone, have been evaluated as treatments for acute postoperative ileus. There are six randomized controlled trials supporting the use of alvimopan; however, the trials do not meet reporting guidelines, and meaningful clinical benefit remains uncertain.¹¹ Methylnaltrexone is currently under investigation for treatment of opioid-induced gut dysmotility, though two phase III trials evaluating its use for postoperative ileus found no benefit.¹²

■ PREVENTION

Opioid use should be limited in favor of alternative agents such as nonsteroidal antiinflammatory drugs (NSAIDs) and intravenous acetaminophen. NSAIDs have been shown to reduce postoperative nausea and vomiting as well as improve GI transit in several studies.¹³ Acetaminophen may also be useful in limiting narcotic use, particularly

FIGURE 27-1 ■ (A) Ileus. Abdominal radiograph shows multiple air-filled dilated loops of small bowel as well as an air-filled colon and rectum. (B) Small bowel obstruction. Abdominal radiograph shows dilated loops of small bowel and multiple air/fluid levels. Small bowel has a paucity of gas and no evidence of air within the colon.

FIGURE 27-2 ■ **Small bowel obstruction.** Abdominal computed tomography scan demonstrates a clear transition point between the dilated and decompressed small bowel.

when NSAIDs are contraindicated.¹⁴ Epidural analgesia may be the best choice for postoperative pain control after abdominal operations as this modality can shorten the period of GI dysmotility.¹⁵ To be most effective, epidural catheters should be placed at the midthoracic level, and epidural agents should be administered intraoperatively and continued for at least 48 hours postoperatively.

Chewing gum may hasten postoperative bowel recovery as demonstrated by multiple trials in patients who have undergone abdominal surgeries.¹⁶ A large systematic review demonstrated decreased time to passage of flatus and bowel movement, as well as decreased length of stay. Although the review was somewhat limited by the quality of studies included, there are no known adverse consequences associated with chewing gum, and it should therefore be considered.

KEY POINTS

1. Ileus is defined as the disruption of normal coordinated propulsive motor activity of the gastrointestinal tract due to a nonmechanical cause and is common in the postoperative period.
2. Symptoms of ileus include abdominal distention, bloating, diffuse abdominal pain, nausea, vomiting, inability to tolerate an oral diet, and inability to pass flatus or stool.
3. If ileus is prolonged, it must be distinguished from a mechanical bowel obstruction, and an underlying pathologic cause must be sought.
4. Treatment is largely supportive, along with the identification and remediation of any inciting factors.
5. Limiting postoperative opioid use and utilizing a thoracic epidural for pain control help prevent ileus following abdominal operations.

Diarrhea is one of the most common abnormal manifestations of gastrointestinal (GI) dysfunction in the intensive care unit (ICU); the reported incidence is between 2% and 63%.¹ Diarrhea is best defined as bowel movements that, owing to increased frequency, abnormal consistency, or increased volume, cause discomfort to the patient or the caregiver. This definition demonstrates the subjectivity in diagnosing diarrhea, a fact that complicates interpretation of the literature and limits applicability of guidelines. The impact of diarrhea on patient care in the ICU, including its cost in morbidity and mortality, is unknown. However, it is undeniable that diarrhea remains a persistent problem in many ICUs.

CRITERIA

Several criteria are used to diagnose diarrhea:

1. Abnormal frequency. Normal frequency is described as one or two bowel movements per day and is in part determined by the amount of fiber in the diet. Three or more bowel movements per day are considered abnormal.¹
2. Abnormal consistency. Abnormal consistency is described as either nonformed stool or stool having excessive fluid content that causes "inconvenience" to the patient, nursing staff, or caregiver. Normal stool water content is 60% to 85% of the total weight.¹
3. Abnormal amount. Stool amount and volume vary significantly with the amount and type of enteral intake. Insoluble fiber adds a significant amount of bulk volume. A "normal" amount is considered to be approximately 200 grams per day (g/d).¹ Abnormal amounts are considered to be greater than 300 g/d, or volumes greater than 250 mL/d.^{1,2}

To date, clinicians are lacking a consistent scale or index that allows a reliable and practical way of measuring stool volume, consistency, and frequency. In its absence, the bedside nurse remains the most reliable person to diagnose the presence of diarrhea.

PATHOPHYSIOLOGY

Bowel movements with normal physiologic volume, consistency, and frequency are the result of a GI tract that integrates motility, secretion, and absorption of fluids and adapts to the quality of the food bolus given. The result is a fecal bolus that is produced once or twice every 24 hours and has consistency and fluidity within the boundaries of normal.

Diarrhea results when there is a disorder of GI physiology or when GI tract function is incapable of handling the food bolus. There are several classifications of diarrhea, suggesting that no classification is ideal at helping the clinician plan for patient care. Perhaps the most useful approach is to classify diarrhea according to alterations of physiologic events:

1. Increased fluid secretion that overwhelms absorption. On average, up to 9 L of fluid is secreted into the GI lumen in addition to the normal oral intake. Less than 1% of that fluid is contained in stool, owing to the amazingly large absorptive capacity of the small and large bowel. Within the intestinal mucosa, passive and active transport of sodium determines the amount of water that is absorbed. Stimulation of the active secretion of fluids into the GI lumen occurs when intracellular levels of the second messenger,

cyclic adenosine monophosphate (cAMP), increases within enterocytes. Increased intracellular cAMP concentration promotes chloride secretion.³ Thus, diarrhea caused by excessive secretion of fluids is called *secretory diarrhea*. Secretory diarrhea characteristically contains large amounts of fluid and is described as watery. Secretory diarrhea is observed in certain infectious diseases such as cholera or infections with rotavirus. Secretory diarrhea also can be observed in endocrine disturbances associated with carcinoid syndrome or vasoactive intestinal peptide (VIP)-secreting tumors.

2. Increased mucous secretion from the large bowel. Overproduction of mucus by the large bowel can lead to development of diarrhea. Excessive mucus secretion is observed in colonic infections such as *Clostridium difficile* colitis and amebiasis.⁴ The incidence of infectious diarrhea in the ICU is unknown.
3. Contaminated food products. Of particular concern is the contamination of the food being given in the ICU. Contamination of enteral formulas can occur at multiple levels, including preparation of the enteral product, use of "open units," addition of modular dietary components, and contamination of the enteral access port (i.e., feeding tube, gastrostomy tube). The incidence of diarrhea due to contaminated feeding tubes is unknown.
4. Diarrhea due to increased osmotic load. Many substances that are taken orally and are not fully absorbed can exert a significant osmotic force, overwhelming the physiologic absorptive capacity of the GI tract. A significant number of patients with diarrhea in the ICU fall into this category.
 - a. Osmotic diarrhea caused by medications. Sorbitol is frequently and inadvertently given to patients in the ICU as a means of preparing many medications for delivery via feeding tubes and is an often overlooked culprit causing diarrhea.⁵ Other osmotic agents include Golytely and magnesium-containing medications.
 - b. Incomplete digestion and malabsorption. The incidence of malabsorption in the ICU is unknown. However, there are many instances where malabsorption should be considered as a cause of diarrhea in the critically ill patient. These include:
 - i. Incomplete protein digestion (azotorrhea). Protein digestion occurs mainly in the stomach by pepsin (only activated at low pH) and hydrochloric acid. In the ICU, virtually all patients receive medications to raise intragastric pH, such as histamine receptor type 2 (H₂) blockers or proton pump inhibitors.^{6,7} In addition, feeding tubes frequently "bypass" the stomach, eliminating both gastric acid and gastric proteolytic digestion.
 - ii. Undigested carbohydrates. In addition to sorbitol (see earlier discussion), excessive glucose, lactose, or fructose in tube-feeding formulas can overwhelm the absorptive capacity of the small bowel, causing an osmotic influx into the gut lumen.⁸
 - iii. Undigested fats. Steatorrhea (diarrhea caused by undigested fats) is characteristically observed in patients with pancreatic insufficiency. Inadvertent lack of mixing pancreatic enzymes with the food bolus can occur in patients with intestinal bypass or pancreatic fistulas or in patients who have undergone pancreatectomy. It is also observed in patients with

incomplete bile production, such as patients who have a biliary diversion.

- iv. Excessive dietary load. Diarrhea due to excessive load (overfeeding) of any of the main dietary components (protein, carbohydrate, or fat) can be observed in the ICU. Iatrogenic overfeeding occurs in up to 33% of patients in the ICU and is a result of inappropriate estimations of caloric and protein needs or inadequate metabolic surveillance.⁹ Excessive loads of protein, carbohydrate, or fat also occur with “specialized” formulas that contain altered amounts of one or more of these components. For example, certain diets may contain high amounts of fat, overwhelming digestive and absorptive processes.
- v. Atrophy of the GI tract. Atrophy of the intestinal brush border is associated with decreased capacity of digestion and absorption. Atrophy is observed in malnourished patients; thus, diarrhea is observed commonly in patients with hypoalbuminemia. Atrophy also occurs when enteral intake is interrupted for more than a few days. This is a particular problem in surgical patients when prolonged “bowel rest” is ordered.
5. Abnormal motility. Intestinal dysmotility is a frequent problem in the ICU. The use of promotility agents (e.g., erythromycin) can inadvertently cause diarrhea in these patients.
6. Abnormal gut flora. Colonic flora is essential for normal absorption and function of the large bowel. Antibiotics create massive disruptions in colonic flora and can sometimes lead to nosocomial infections with resultant diarrhea. Currently, *C. difficile* is the leading cause of nosocomial diarrhea and accounts for 30% of patients with antibiotic-associated diarrhea.¹⁰ The gut microflora can be modulated through the use of probiotic agents, but this topic is under intense investigation, and no current guidelines exist regarding their use to treat or prevent diarrhea in ICU patients.¹¹

CLINICAL CONSEQUENCES OF DIARRHEA

Untreated, diarrhea can lead to multiple problems. These include:

1. Wound breakdown and secondary soft-tissue infection. Diarrhea can cause a moist, contaminated environment; if left untreated, this can lead to skin breakdown and eventual soft-tissue infection. Particularly concerning are the presence of decubitus ulcers; diarrhea can be either a causative factor or can worsen or complicate management.
2. Fluid and electrolyte disturbances are particularly frequent in patients with secretory diarrhea. In these patients, clinicians need to pay attention to fluid replacement and correct metabolic acidosis and/or hypokalemia.
3. Malnutrition. Inadequate nutrient absorption can lead to poor nutrient utilization.
4. Increased workload for nurses and caregivers. Diarrhea imposes a substantial burden on nurses and other caregivers. In addition, the presence of a soiled patient evokes a sense of poor quality of care. Maintaining a clean patient with diarrhea requires additional ICU personnel time and resources that could be better used.

DIAGNOSIS

Careful and complete evaluation of diarrhea is necessary for good patient care. Unfortunately, diarrhea is often ignored or hastily “treated” while clinicians pay more attention to other organ systems. Diagnostic laboratory tests often do not exist, making it ever more difficult to identify and treat the patient. We propose the following approach:

1. Does the patient really have diarrhea? Clinicians rarely will question the diagnosis of diarrhea. Most diagnoses are probably made without a clear understanding of the definition of diarrhea. A concerted effort to diagnose diarrhea by all members of the ICU staff

is essential. The creation of scales or indices could become particularly useful as a means of communication. These could also aid in following the effectiveness of treatment.

2. Can an iatrogenic cause explain the presence of diarrhea?
 - a. Is the patient on prokinetic agents or stool softeners?
 - b. Is the patient receiving medications with high concentrations of sorbitol?
 - c. Is the patient being overfed?
 - d. Is the patient intolerant to any of the components of the diet?
 - e. Is a specialized diet providing an excessive amount of a substance (e.g., fat) that the patient is having difficulty digesting?
 - f. Is bypassing the stomach or inhibiting acid secretion affecting the digestion of protein?
 - g. Is the patient on any other medication that can cause diarrhea?
3. Assessing the patient's absorptive or digestive capacity.
 - a. Does the patient have gut atrophy, as seen with prolonged bowel rest? Would this patient benefit from an intestinal rehabilitation strategy?
 - b. Is the patient malnourished?
 - c. Does the patient have a condition (e.g., pancreatitis) that alters the secretion of digestive enzymes?
 - d. Does the patient have a chronic disease process (e.g., short gut syndrome) that alters absorption?
4. Does the patient have an infection?
 - a. Is there any evidence of contamination of feeding tubes? Are you using a closed system? How often is it being changed?
 - b. Is there cause for nosocomial bowel infection? Is the patient's *C. difficile* toxin negative?
 - c. Has colonic flora been altered significantly with antibiotics?

TREATMENT

Treatment is dependent on identification of the underlying cause. One or several reasons for the presence of diarrhea generally can be identified. Once identified, the causes of diarrhea should be eliminated, modified, or treated. In particular, iatrogenic causes of diarrhea should be identified and corrected whenever feasible. For example, prolonged courses of prophylactic antibiotics are no better than short courses for the prevention of surgical site infections; therefore, adherence to current guidelines to limit antibiotics is important.^{12,13}

Modification of the diet may be important if the GI tract is being overwhelmed with high quantities of a particular nutrient. This is particularly important for patients receiving formulas that deliver excessive fat loads.

Digestive enzymes such as pancreatic enzymes or bile substitutes should be supplemented when the disease process (or treatment) is associated with decreased production of these enzymes.

Agents that inhibit GI motility, such as loperamide, should be used with caution. These drugs are often ordered empirically and may worsen underlying pathology, especially when the causative agent is infectious.

Bulk-forming agents are sometimes given to patients to improve the consistency of the fecal bolus. These agents have to be used in the appropriate amount, since they can also be a cause of diarrhea.¹⁴

Antibiotics to treat infectious diarrhea also should be used with caution. If the diarrhea is causing minimal discomfort and is of no physiologic consequence, waiting for the arrival of results of tests for *C. difficile* may be advised.¹⁵

Restoring normal colonic flora has become an increasingly frequent practice in the ICU. Provision of prebiotics and probiotics in different presentations is now being suggested, but the implications of such therapies are not clear and require further investigation.^{11,16} Soluble fiber may have a role in restoring normal colonic function and flora.

Stopping or decreasing the rate of enteral nutrition is often done; however, this is only advocated if the patient is being overfed or exhibits intolerance to the diet. Only under exceptional circumstances should stopping oral intake and giving total parenteral nutrition be advocated as a treatment for diarrhea.

CONCLUSION

Diarrhea is a poorly studied clinical manifestation of GI dysfunction in the ICU. The true incidence of diarrhea in ICU patients is unknown

because of the lack of a universally accepted definition or a concerted effort to study the problem. Despite these limitations, when discovered, diarrhea can be effectively treated with careful clinical evaluation of the patient and easily implemented therapeutic measures.

The clinical diagnostic approach to rash and fever in the intensive care unit (ICU) depends on whether the rash and fever were community or nosocomially acquired. Community-acquired rash and fever are best approached by considering the distribution and characteristics of the rash.¹⁻⁵ Rashes are visible clues to infectious or noninfectious disorders. In addition to the rash and fever, often the associated findings, such as history, physical examination, and laboratory abnormalities, are keys to the correct diagnosis.^{1,4,6-8}

Nosocomially acquired rashes have more limited differential diagnostic possibilities.⁶ The clinician should determine whether the rash and fever represents the primary clinical problem or is a superimposed finding unrelated to another process. For example, ICU patients admitted for acute myocardial infarction can develop a drug rash from an antiarrhythmic medication, beta-blockers, diuretics, or sulfa-containing stool softener (Colace).^{1,3}

Acutely ill patients with a rash and fever in the ICU should have the benefit of an infectious disease consultation by an experienced infectious disease clinician.^{1,3} Both community and nosocomially acquired rash and fever are best diagnosed using the clinical syndromic approach in which associated clinical findings, not the appearance of the rash alone, are the main determinants of arriving at the correct diagnosis.^{5,7}

COMMUNITY-ACQUIRED RASH AND FEVER

Patients admitted to the ICU from the community with rash and fever are best approached by the type and distribution of the rash.² The degree of fever relative to the pulse rate and fever pattern are also important diagnostic considerations.^{3,9}

Petechial/Purpuric Rash and Fever

While petechial and purpuric rashes are common causes of community-acquired rash and fever, petechiae can accompany a variety of systemic infections, as well as a variety of noninfectious disorders.¹⁰⁻¹² Rash and fever is often potentially life-threatening (e.g., meningococcemia [MC] with or without meningitis, Rocky Mountain spotted fever [RMSF], dengue fever [DF], and arboviral hemorrhagic fevers), and patients should have the benefit of a diagnostic evaluation by an experienced infectious disease consultant.^{1,4,10,11}

The two most common infectious diseases presenting with a petechial/purpuric rash are MC and RMSF. RMSF should be suspected with a history of recent tick exposure and a characteristic location and distribution of the rash. Importantly, RMSF is the only infectious exanthema that begins on the wrists and/or ankles.¹³⁻¹⁵ In contrast, the rash of MC is asymmetrical with irregularly shaped painful petechial or purpuric lesions.^{1,8,11}

Post-splenectomy sepsis (PSS) can resemble meningococcemia but only occurs in patients with impaired or absent splenic function.^{1,4,11}

Clinicians should be familiar with the disorders associated with the diminished splenic function. A key clinical clue to impaired splenic function is the presence of Howell-Jolly bodies or “pocked/pitted” red blood cells in the peripheral smear. The number of Howell-Jolly bodies is inversely proportional to splenic function.^{1,8}

High-grade and continuous *Staphylococcus aureus* bacteremia (methicillin-sensitive/methicillin-resistant [MSSA/MRSA]) from abscesses or acute bacterial endocarditis (ABE) is often accompanied by splinter hemorrhages and petechial or purpuric rashes on the distal extremities.^{1,10,11}

Maculopapular Rashes and Fever

The most common maculopapular rashes and fever associated with serious systemic diseases are toxic shock syndrome (TSS) and systemic lupus erythematosus (SLE). SLE flares can mimic infectious diseases.^{1,4,11} Thus, SLE pneumonitis can mimic community-acquired pneumonia (CAP), and SLE cerebritis can mimic acute bacterial meningitis (ABM). Laboratory studies can differentiate an SLE flare in the absence of infection from an SLE flare with an infection. Typically, SLE flares without infection are accompanied by leukopenia, decreased complement levels, and elevated α_1/α_2 globulins on serum protein electrophoresis (SPEP).^{1,8}

TSS can occur in any patient colonized or infected with a TSS-1-producing strain of *S. aureus*. However, TSS may not be considered when there are no overt signs of clinical infection (e.g., staphylococcal colonization of the nares). TSS also may be due to group A streptococci or *Clostridium sordelli*.^{2,4,11}

Vesicular/Bullous Rashes and Fever

Vesicular eruptions limit the diagnostic possibilities to chickenpox or herpes zoster (shingles) due to varicella zoster virus (VZV). Herpes zoster may be localized (dermatomal) or disseminated.⁵⁻⁷ Prior to the appearance of the vesicular rash and fever, dermatomal herpes zoster can be a difficult diagnostic problem, mimicking many disorders.⁶ Herpes zoster involving the head and neck may be associated with VZV meningitis or encephalitis. Disseminated shingles can resemble chickenpox, but patients with herpes zoster have a prior history of chickenpox.^{1,4,11}

Community-acquired bullous lesions in the ICU may be due to *S. aureus* soft-tissue abscess, *Vibrio vulnificus*, or gas gangrene (clostridial myonecrosis). Except when due to *S. aureus*, all the causes of bullae/fever are painful and tense and accompanied by diarrhea. Clostridial myonecrosis (i.e., gas gangrene) may be present after a crush injury or trauma. The most common cause of bullae and fever is *S. aureus* abscess or pyoderma.¹⁰⁻¹²

The differential diagnostic features of community-acquired rash and fever are presented in tabular form in [Tables 29-1 to 29-10](#).¹⁻¹⁹

|--------------------------|----------------------|----------------------|----------------------|---|---|---|--|
| <i>Vibrio vulnificus</i> | + | — | — | Rash appears <i>hours-days</i> after fever Painful bullous lesions usually on buttocks | Clinical Findings: Fever/chills Watery diarrhea prominent ± abdominal pain Laboratory Findings: Leukocytosis AST(SGOT)/ALT(SGPT): WNL Diagnosis: Clinical appearance/presentation Blood/stool/wound cultures positive for <i>V. vulnificus</i> | Ingestion of water contaminated with “halophilic vibrios” Recent exposure of wound with water contaminated with “halophilic vibrios” | Gas gangrene: No recent colon/pelvic surgery No exposure to “halophilic vibrios” No fever/chills No muscle involvement (myonecrosis) Culture of bullae negative for <i>Vibrio vulnificus</i> Diabetic cSSSIs: Diabetes may develop bullae (without infection) but are not toxemic Diabetes with mixed aerobic/anaerobic infections are febrile but have no muscle involvement (myonecrosis) Diabetes with mixed aerobic/anaerobic with cSSSIs have crepitus/abundant gas on soft-tissue x-rays No acute hemolytic anemia No watery diarrhea Bullous fluid foul smelling Bullous fluid/soft-tissue cultures positive for aerobes/anaerobes (not Clostridium) |

ALT, alanine aminotransferase/SGPT, serum glutamic-pyruvic transaminase; AST, aspartate aminotransferase/SGOT, serum glutamic-oxaloacetic transaminase.

NOSOCOMIAL-ACQUIRED RASH AND FEVER

Petechial/Purpuric Rash and Fever

Staphylococcal bacteremia (high-grade and continuous) is usually related to an intravascular or interventional procedure or device.^{1,3} Staphylococcal bacteremia or ABE presents initially with petechial or purpuric lesions that later can become hemorrhagic and/or gangrenous. The diagnosis is suggested by the peripheral location of these irregular, painful lesions in the setting of high-grade and continuous staphylococcal bacteremia.^{1,4,11}

An underrecognized but important cause of nosocomial rash and fever is cholesterol emboli syndrome (CES).²⁰ Cholesterol emboli may be released into the systemic circulation during or following cardiovascular procedures. CES presents as a petechial or purpuric rash with a livedo reticularis-like appearance.^{1,8} The rash occurs on the trunk and extremities and may be accompanied by signs of cholesterol emboli to other organs such as the heart (myocardial infarction), pancreas (acute pancreatitis), kidneys (acute renal failure), or central nervous system (stroke). Excluding drug rash and fever, cholesterol emboli syndrome is the only acute rash in the ICU associated with peripheral eosinophilia.^{8,20}

Drug rashes are drug hypersensitivity reactions presenting with a rash and fever. Most patients who develop drug rashes do so after receiving new medications in the hospital, but some develop drug rash and fever years after taking sensitizing chronic medications. Drug rashes are generalized, maculopapular or petechial, and may be pruritic. Fever is usually present and may be high (>102°F), regularly accompanied by relative bradycardia.^{8,9} Mild increases in serum transaminase levels and eosinophils in the blood smear are common findings.⁸ The clinical difficulty with drug rash and fever is distinguishing it from underlying medical disorders. Even after discontinuing the sensitizing drug, the rash and fever may take days or weeks to resolve.^{1,3,4,9}

Maculopapular Rashes and Fever

Maculopapular rash due to surgical TSS is uncommon. Typical surgical TSS occurs from wound infection several days after surgery. A key clinical clue is that drainage from the wound is serosanguineous rather than purulent.^{5,7,11,12}

Vesicular/Bullous Rashes and Fever

Particularly following distant extremity trauma or distal abdominal surgery, gas gangrene should be considered in the differential diagnosis.^{3,6} In patients with gas gangrene (i.e., clostridial myonecrosis), the vesicular or bullous eruptions spread rapidly (over minutes to hours). The skin near the bullous lesions is tense and extremely tender, and the fluid in the lesions is not foul smelling. Patients with gas gangrene are afebrile or have only a low-grade fever, but these patients often have watery diarrhea.^{1,3} A key clinical clue to gas gangrene is rapidly progressive hemolytic anemia due to lysis of red blood cells by clostridial lethicinases.^{1,4,11} On physical examination, gas in tissues is not clinically detectable or obvious and is not a feature of gas gangrene. On a computed tomography (CT) scan, small gas bubbles may be visible along the muscle planes.^{1,3} Large collections of gas in the soft tissues on imaging studies should suggest a mixed aerobic-anaerobic infection by nonclostridial gas-producing organisms. Mixed aerobic-anaerobic soft-tissue infections are most common in diabetics and do not involve muscle (myonecrosis).^{1,3,10}

Fever is usually prominent with mixed aerobic or anaerobic soft-tissue infections, but clostridial gas gangrene characteristically is associated with little or no fever. The differential diagnosis of nosocomial rash and fever is presented in [Tables 29-11 to 29-14](#).^{1,4,10,11}

The diagnostic approach to rash and fever depends on correctly correlating the location and characteristics of the rash with associated nondermatologic features, such as physical examination, laboratory findings, or both to arrive at a clinical syndromic diagnosis ([Table 29-15](#)).¹⁻²⁰

Chest pain in the intensive care unit (ICU) is a somewhat different entity from chest pain seen in the office, inpatient ward, or emergency department. The keys to management of chest pain in the ICU are rapid assessment and treatment of immediately life-threatening conditions, careful consideration of the differential diagnosis, a logical evaluation plan, and empiric treatment while pursuing a definitive diagnosis.

INITIAL APPROACH

Several life-threatening conditions can cause chest pain in the critically ill, and the initial approach should focus on prompt evaluation and resuscitation of the airway, breathing, and circulation. Assess the patient's level of consciousness, palpate the pulse, and listen to the breath sounds and heart. Obtain vital signs, including oxygen saturation by pulse oximetry, and ensure that the patient is on a cardiac monitor and has adequate intravenous (IV) access. Adhering to this algorithmic approach (Fig. 30-1) in patients with chest pain will ensure that critical conditions such as hypoxemia, hypotension, tension pneumothorax, and unstable ventricular arrhythmias are quickly identified and treated. These conditions, as well as the life-threatening causes of chest pain discussed below, are covered in greater detail in other chapters in this textbook.

HISTORY

After the initial evaluation and stabilization, obtain a more detailed history. If the patient can communicate, start with an open-ended question like "What's going on, Mr. Jones?" Physicians typically interrupt patients within 23 seconds, but one should resist this temptation and allow the patient to describe his or her symptoms.¹ Physicians often neglect to ask even basic questions about the quality of chest pain, as was shown in a study of patients with aortic dissection, and this omission is associated with a delay in diagnosis.² The mnemonic OLDCAAR can help avoid this mistake (Table 30-1). Ask the bedside nurse about recent changes in the patient's condition (e.g., changes in mental status, respiratory pattern, or recent medications). Last, a quick "chart dissection" should be performed, focusing on the findings noted on initial presentation, reason for ICU admission, past history, and recent progress notes.

PHYSICAL EXAMINATION

Inspect the chest for asymmetric excursions, rashes, or obvious sources of pain, such as chest tubes. Palpate the chest and neck for crepitus, which can result from a pneumothorax or pneumomediastinum. Check for pulsus paradoxus and jugular venous distention. Assess for asymmetry in the carotid, femoral, or radial pulses, which can be a sign of aortic dissection. If the breath sounds are asymmetrical, hyperresonance to percussion may confirm a pneumothorax. Cardiac auscultation may reveal a friction rub from pericarditis, "crunching" sounds from mediastinal emphysema (Hamman's sign), a systolic murmur of aortic stenosis, or an aortic insufficiency murmur from a proximal aortic dissection. A focused examination also should include the abdomen to avoid missing an abdominal catastrophe masquerading as chest pain. Unfortunately, the physical examination has its limitations, and further diagnostic testing is often necessary.

DIAGNOSTIC ADJUNCTS

In the absence of an obvious cause of chest pain (e.g., shingles), a portable chest x-ray (CXR) and electrocardiogram (ECG) should be obtained. Serial cardiac enzymes should be strongly considered to exclude a myocardial infarction (MI). The ECG is often nonspecific but occasionally will show evidence of acute coronary syndrome (ACS), pericarditis, or pulmonary embolism (PE). The CXR is a useful screening tool for life-threatening causes of chest pain, including aortic dissection, pneumothorax, and esophageal rupture. Both the ECG and CXR should be compared with those performed prior to the onset of pain. Although the ECG or CXR may be suggestive of a diagnosis, other confirmatory studies may be necessary.

IV contrast-enhanced computed tomography (CT) can help diagnose a number of causes of chest pain, including PE, aortic dissection, esophageal rupture, pneumothorax, and pneumonia. The benefits of CT scanning, however, must be weighed against the risks of transporting a critically ill patient out of the ICU, as well as the potential for causing contrast nephropathy. Ultrasound (including echocardiography) can be rapidly performed with minimal risk to the patient and does not require transport out of the ICU. Pericarditis with associated effusion, wall motion abnormality from MI, aortic stenosis, aortic dissection, and pneumothorax are all within the diagnostic realm of ultrasound. Ultrasound has the added benefit of providing information about cardiac function.

DIFFERENTIAL DIAGNOSES

Two rules to live by:

1. Do not assume the admission diagnosis is correct or all inclusive. Premature closure, that is, failing to consider alternative possibilities after a diagnosis has come to mind, is a common cause of medical error.³ Premature closure likely contributes to the delay in diagnosis described in hospitalized patients with aortic dissection.⁴
2. Do not be biased by the type of ICU to which the patient is admitted. Aortic dissection can present as a stroke, prompting admission to a neurologic ICU, or an acute abdomen can develop in a medical ICU patient. Indeed, a review of abdominal catastrophes concluded that "delays in surgical evaluation and intervention are critical contributions to mortality rate in patients who develop acute abdominal complications in a medical ICU."⁵

Potentially Life-Threatening Causes of Chest Pain

Acute Coronary Syndrome

ACS includes unstable angina and MI with or without ST-segment elevation MI. The classic symptoms of ACS include chest pressure radiating to the left arm, nausea, and diaphoresis, but this history has several limitations with regard to the diagnosis of ACS. Although certain features (pain radiating down the right arm or both arms) are associated with a higher likelihood of ACS, and other characteristics (pleuritic, positional, or sharp pain) with a lesser likelihood, none of these can reliably confirm or exclude the diagnosis.^{6,7} Further complicating matters, the conventional cardiovascular risk factors, including diabetes, smoking, dyslipidemia, hypertension, and a family history,

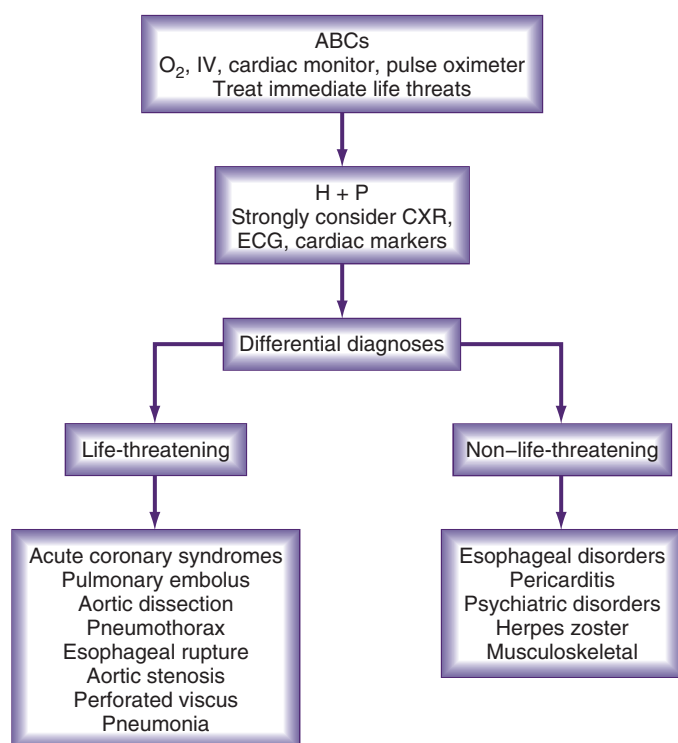

FIGURE 30-1 ■ Approach to chest pain in the ICU. ABC, airway, breathing, circulation; CXR, chest x-ray; ECG, electrocardiogram; H + P, history and physical examination; ICU, intensive care unit; IV, intravenous access.

TABLE 30-1 OLDCAAR Mnemonic for Evaluating Pain

| DOMAIN | SUGGESTED QUESTIONS |
|--------------------------------|---|
| Onset | Sudden or gradual? Maximal pain at onset? |
| Location | Generalized or localized? Can you point with one finger to where it hurts? |
| Duration | When did it start? Just now, or did the pain occur earlier, but you didn't want to bother anyone? Is it constant or intermittent? If intermittent, is there a trigger, or is it random? |
| Character | Sharp? Dull? Ache? Indigestion? Pressure? Tearing? Ripping? |
| Associated symptoms | "Dizzy" (vertiginous or presyncopal)? Diaphoresis? Palpitations? Dyspnea? Nausea or vomiting? |
| Alleviating/aggravating | Position? Belching? Exertion? Deep breathing? Coughing? |
| Radiation | To the back? Jaw? Throat? Arm? Neck? Abdomen? |

predict the development of heart disease over years in asymptomatic patients but may be less useful in predicting ACS in patients with acute chest pain.⁸ Reduction in pain after the administration of nitroglycerin is also not a reliable indicator of cardiac chest pain.⁹ Thus, ACS should almost never be excluded as a cause of chest pain based on the symptoms alone.

Physical examination findings in patients with ACS may include signs of left ventricular dysfunction, such as hypotension, jugular venous distention (JVD), and an S₃ or S₄ heart sound. The ECG should be examined for ST segment elevation or depression, Q waves, and

T-wave inversions. The ECG has a low sensitivity for diagnosing MI, but yield increases with serial ECGs. Given the limitations of the ECG and history and examination findings, cardiac enzymes should be measured in most ICU patients with chest pain.

All patients suspected of having ACS should be placed on oxygen and, if not contraindicated, treated with aspirin (clopidogrel or ticagrelor if there is aspirin allergy). Sublingual nitroglycerin and IV morphine should be used to relieve pain if the systolic pressure is above 90 mm Hg. Further treatment of ACS is primarily dictated by ECG findings and the patient's clinical status. It may include emergency percutaneous coronary intervention (the preferred strategy) or fibrinolysis in the setting of ST segment elevation when on-site cardiac catheterization is not available and the bleeding risk is acceptable. Adjunct therapies, depending on cardiac findings and the treatment administered may include dual antiplatelet therapy (aspirin plus clopidogrel, prasugrel, or ticagrelor), a beta-blocker, statin, angiotensin-converting enzyme inhibitor or angiotensin receptor antagonist, and aldosterone receptor antagonist.

Pulmonary Embolism

Approximately 1% to 2% of ICU patients develop deep vein thrombosis (DVT) or PE, but the true incidence is probably higher.¹⁰ Unrecognized PE carries a high mortality, but survival improves dramatically with prompt diagnosis and treatment. Chest pain due to PE is usually pleuritic and often associated with dyspnea, hemoptysis, cough, or syncope.¹¹ ICU patients often have one or more risk factors for PE, including immobility, advanced age, recent surgery or trauma, malignancy, and central venous catheterization. Do not be deterred from evaluating for PE in patients receiving subcutaneous heparin, as in one study of patients in intensive care, two-thirds diagnosed with DVT and PE were receiving prophylaxis at the time of diagnosis.¹⁰

Physical examination findings are generally nonspecific in PE. Unexplained tachypnea or tachycardia may be the only diagnostic clues. Hypoxia is often present but is not a universal finding, and its absence cannot exclude PE. A large PE may present with hypotension or cardiovascular collapse. Signs of pulmonary hypertension and right heart failure, such as a loud second heart sound (P₂), JVD, or a right-sided S₄ heart sound may be present. Lung examination may reveal crackles, decreased breath sounds, wheezing, rhonchi, or a pleural friction rub.

An elevated arterial-alveolar gradient may be noted on blood gas analysis, but this is a nonspecific finding in the critically ill. The ECG is often normal, but it may show sinus tachycardia, right axis deviation, nonspecific ST segment and T-wave changes, or a right bundle branch block.¹² The CXR can be normal but more commonly reveals nonspecific findings such as pleural effusion, infiltrates, or atelectasis.¹³ Although D-dimer testing has been used to rule out venothromboembolic disease in outpatients with a low likelihood of this diagnosis, the D-dimer assay does not appear to be a particularly useful diagnostic tool in the ICU setting.¹⁴ The sensitivity of transthoracic echocardiography (TTE) for PE varies considerably, but the test can be useful in patients who have large clots that are of hemodynamic significance. In such cases, TTE can be performed rapidly at the bedside when it is unsafe to transport patients out of the ICU. TTE has the added benefit of assessing the response to thrombolytics by evaluating right heart function and changes in pulmonary artery pressure.¹⁵ A ventilation/perfusion scan can be time consuming and difficult to perform in mechanically ventilated patients, and interpreting it may be challenging in the presence of other lung pathology.¹⁶ An IV contrast-enhanced CT of the chest can be performed rapidly, and newer scanners have high sensitivity and specificity, making this the diagnostic study of choice in most ICU patients.

Initial treatment of patients with confirmed PE involves anticoagulation with subcutaneous low-molecular-weight heparin or fondaparinux, IV unfractionated heparin, or the newer oral factor Xa inhibitors rivaroxaban or apixaban. Patients with hemodynamic instability due to PE may require thrombolysis or surgical- or catheter-mediated embolectomy.¹⁷

Thoracic Aortic Dissection

Aortic dissection results from a tear in the aortic intima, allowing blood to dissect between the intima and adventitia. The Stanford system classifies dissections as type A (involving the ascending aorta) or type B (not involving the ascending aorta). Risk factors include hypertension, male sex, pregnancy, advanced age, atherosclerosis, cocaine use, intraaortic catheterization, Ehlers-Danlos syndrome, Turner syndrome, high-intensity weight lifting, chest trauma, and giant cell arteritis.¹⁸ Patients younger than 40 years are more likely to have Marfan syndrome, Loeys-Dietz syndrome, bicuspid aortic valve, prior aortic surgery, or aortic aneurysm.¹⁹ The mortality rate is as high as 1% to 2% per hour from symptom onset, and the history remains critical to early diagnosis.²⁰ Clinicians correctly suspect aortic dissection in more than 90% of cases when questions about quality, radiation, and intensity of the pain are asked. If one or more of these questions is omitted, the correct diagnosis is missed in over half of cases.² Many patients complain of sudden onset of chest pain that radiates to the back or abdomen. Contrary to popular belief, patients more commonly describe their pain as sharp, rather than tearing.¹⁹ Dissection can extend into any of the major aortic branches, causing a multitude of clinical presentations owing to ischemia of the brain, heart, kidney, spinal cord, or gut.

Certain physical examination findings should raise the suspicion of aortic dissection. About one-third of patients have pulse deficits in the carotid, radial, or femoral arteries, and some have focal neurologic deficits related to cerebral or spinal cord ischemia.¹⁸ Hypotension often occurs with type A dissection, whereas hypertension is more commonly seen in type B dissection.²⁰ A significant difference in systolic blood pressure (>20 mm Hg) between the upper extremities may be seen with dissection, but this is not a pathognomonic finding. A diastolic murmur of aortic insufficiency can result from retrograde dissection into the aortic valve.

The ECG may be normal or show nonspecific ST segment or T-wave changes or left ventricular hypertrophy secondary to hypertension. Rarely, the ECG reveals evidence of an MI from retrograde dissection into a coronary artery. Over 90% of patients will have some abnormality on CXR, such as widening of the mediastinum, an abnormal aortic contour, pleural effusion, or displacement of intimal aortic calcification from the outer border of the aortic knob.²¹ Therefore, it behooves the clinician to scour the CXR for these findings when considering aortic dissection as a cause of chest pain. The diagnosis can be confirmed with CT, magnetic resonance imaging (MRI), or transesophageal echocardiography, all of which have high sensitivity and specificity. The choice of diagnostic study will depend on physician preference and the risks involved. Initial management should focus on blood pressure control, usually with beta-blockers and a potent vasodilator such as nitroprusside²⁰ and emergent cardiothoracic surgical consultation.

Pneumothorax

Pneumothorax is caused by air from the alveoli or the atmosphere entering the potential space between the parietal and visceral pleura. Pneumothorax in the ICU is often iatrogenic, resulting from mechanical ventilation (particularly with acute respiratory distress syndrome), attempts at central venous catheterization, thoracentesis, tracheostomy, or bronchoscopy.²² Virtually any lung pathology can contribute to a pneumothorax, but a ruptured bleb from chronic obstructive pulmonary disease is the most common culprit. Patients with pneumothorax typically complain of the sudden onset of ipsilateral pleuritic chest pain with associated dyspnea.

Chest examination may reveal palpable crepitus, decreased breath sounds, decreased chest wall excursion, or hyperresonance to percussion on the affected side. Vital signs may be significant for tachycardia, hypoxia, or tachypnea. Patients with a tension pneumothorax classically have tracheal deviation, JVD, and hypotension. Patients on mechanical ventilation can have increased peak inspiratory airway pressures. The signs of pneumothorax are nonspecific, and any signifi-

cant deterioration in a patient on a ventilator should prompt a diagnostic evaluation for pneumothorax.

CXRs are often performed in the semiupright or supine position in the ICU, whereas the classic finding in pneumothorax of a visceral pleural line is often seen only on upright CXR. In supine patients, a deep sulcus sign may be seen where the costophrenic angle extends more inferiorly than normal as air collects in this space. Alternatively, a sharp delineation of the cardiac silhouette from the lucency of an anteromedial pneumothorax may be seen. In an experienced operator's hands, ultrasound can effectively rule out a pneumothorax in seconds.²³

Because of a high rate of conversion to tension pneumothorax in patients on mechanical ventilation, prompt diagnosis and treatment are critical. Treatment involves evacuation of air from the pleural space, usually through tube thoracostomy. In patients with hemodynamic compromise from a suspected tension pneumothorax, treatment with immediate needle thoracostomy, followed by tube thoracostomy, should not be delayed while waiting for a CXR.

Esophageal Rupture

A full-thickness tear of the esophagus carries high mortality owing to the intense inflammatory response to gastric contents in the mediastinum, secondary bacterial infection, and subsequent sepsis and multi-system organ failure. Most cases of esophageal perforation are caused by upper gastrointestinal tract endoscopy.²⁴ The risk of esophageal injury from a diagnostic endoscopy is low but increases dramatically when interventions such as dilation or stent placement are performed. Esophageal rupture may be caused by other procedures commonly performed in the ICU, including nasogastric or tracheal intubation. Spontaneous rupture of the esophagus (Boerhaave syndrome) occurs from a sudden increase in intraluminal pressure, usually from vomiting or retching. Patients with esophageal disease such as cancer, Barrett's esophagus, strictures, prior radiation, and varices are particularly vulnerable to rupture. With thoracic perforations, the pain localizes to the substernal or epigastric area, but it may occur in the neck with cervical perforations. Other associated symptoms include dysphagia, odynophagia, and dyspnea.

The patient is often febrile. Crepitus can be felt in the neck with perforation of the cervical esophagus. Mediastinal emphysema can sometimes be detected by a crunching sound on cardiac auscultation (Hamman's sign). A CXR often reveals subcutaneous emphysema, pneumomediastinum, pneumothorax, or pleural effusion. The CXR is abnormal in almost 90% of cases but may be normal early after the perforation occurs.²⁴ A water-soluble contrast study of the esophagus or a CT scan of the chest can be performed in cases where there is a high clinical suspicion and the CXR is nondiagnostic.

Treatment may involve operative repair, endoscopic therapy, or conservative management with broad-spectrum antibiotics and close observation.

Aortic Stenosis

Aortic stenosis causes left ventricular outflow obstruction, which leads to left ventricular hypertrophy. Aortic stenosis may result from a congenitally abnormal (bicuspid) valve, rheumatic heart disease in young adults, or from valvular calcification in the elderly. Clinical manifestations of aortic stenosis, including angina, congestive heart failure, and syncope, occur when the hypertrophied left ventricle can no longer overcome the valvular stenosis or when the hypertrophy itself causes diastolic dysfunction or excessive myocardial oxygen demand leading to ischemia.

Physical examination features of aortic stenosis include narrow pulse pressure, a delayed and slow rise of the carotid pulse (pulsus tardus et parvus), a systolic murmur at the right second intercostal space often radiating to the carotid arteries, and an S₄ heart sound (if patients are in sinus rhythm). CXR and ECG may show signs of left ventricular hypertrophy, but the diagnostic study of choice is a Doppler echocardiogram.

Definitive therapy involves valve replacement, either surgical or in select cases via transcatheter aortic valve replacement. Temporizing

management focuses on cautiously decreasing afterload with vasodilators. Close hemodynamic monitoring is essential when using vasodilators because of the risk of hypotension. Angina and congestive heart failure are treated with oxygen and the careful administration of nitrates, morphine, and diuretics. Occasionally, balloon aortic valvuloplasty may be used to bridge patients until they can undergo surgical or transcatheter valve replacement.²⁵

Miscellaneous

Other causes of potentially life-threatening chest pain in the ICU include pneumonia and acute abdominal processes. Pneumonia is often accompanied by pleuritic chest pain or shoulder pain referred from diaphragmatic irritation. A perforated ulcer can sometimes present with chest pain, and the diagnosis is often made when free air is incidentally discovered under the diaphragm on an upright CXR.

Non-Life-Threatening Causes of Chest Pain

The following causes of chest pain should be considered only after life-threatening causes have been excluded.

Esophageal Disorders

In patients with noncardiac chest pain, gastroesophageal reflux disorder and esophageal motility disorders (e.g., esophageal spasm) are common. Esophageal disease is associated with pain precipitated by lying flat, postprandial pain, heartburn, or dysphagia. Owing to the shared innervation of the heart and esophagus, visceral pain originating from these two organs can be similar in character. Relief of symptoms after a "GI cocktail" cannot be relied upon to identify chest pain as noncardiac in origin.²⁶ Confirmatory testing with esophageal manometry and esophageal pH monitoring can be performed, but a trial of a proton pump inhibitor may be a more practical diagnostic approach.²⁷ Last, a nasogastric tube with the distal tip in the esophagus can produce chest pain; this is easily remedied by advancing the tube distally into the stomach.

Musculoskeletal Disorders

The chest wall is a common source of pain in patients without a cardiorespiratory etiology of their symptoms. Pain from costochondritis is often reproduced with palpation or with arm movement. Up to 15% of patients with MI also have chest wall tenderness, so this finding does not exclude ACS.²⁸ Most cases of costochondritis are self-limiting and treated with nonsteroidal antiinflammatory drugs (NSAIDs). ICU patients may have other causes of chest wall pain, including rib fractures, chest tubes, postoperative pain after cardiothoracic surgery, or an intercostal muscle strain from coughing.

Pericarditis

Pericarditis is a relatively rare cause of chest pain in the inpatient setting.²⁹ The condition most commonly results from viral or idiopathic causes, but other etiologies include bacterial infections, malignancy, tuberculosis, uremia, autoimmune diseases, transmural MI (Dressler's syndrome), and cardiac surgery (postpericardiotomy syndrome). Chest pain from pericarditis is typically pleuritic, sharp, and retrosternal and radiates to the back, neck, or arms. The pain is often relieved by sitting forward and exacerbated by lying flat. Although uncomplicated pericarditis is not generally life threatening, pericardial inflammation can lead to pericardial effusion and cardiac tamponade if the effusion is large or acute.

A pericardial friction rub is highly specific for pericarditis and is present in the majority of cases. A classic pericardial rub with systolic and diastolic component sounds similar to hair being rubbed together

and is best heard with the diaphragm of the stethoscope over the left sternal border, with the patient sitting forward. Beck's triad (JVD, hypotension, muffled heart tones) is the classic description of pericardial tamponade, but unexplained tachycardia and tachypnea may be early signs. Pulsus paradoxus, or a fall in systolic blood pressure by more than 10 mm Hg with inspiration, is often seen in tamponade but is nonspecific.

ECG findings can clinch the diagnosis of pericarditis. Both MI and pericarditis may result in ST segment elevation, but with pericarditis, ST segment depression is typically absent in the reciprocal leads. Absence of Q waves, diffuse concave ST segment elevation, and PR depression strongly favor pericarditis.²⁹ Careful ECG review, auscultation, and history are key to distinguishing ACS from pericarditis and avoiding the potentially fatal complication of administering thrombolytics to a patient with pericarditis and precipitating hemotamponade. Electrical alternans and low voltage on the ECG, coupled with cardiomegaly on CXR, strongly favor pericardial effusion. Although the ECG and CXR findings of pericardial effusion can be useful, echocardiography should be performed to confirm the diagnosis.

Treatment is aimed at the underlying etiology. NSAIDs relieve pain and inflammation in cases of viral or idiopathic pericarditis. Colchicine may be used as an adjunct to NSAIDs in reducing bouts of recurrent pericarditis.³⁰ Pericardiocentesis is performed for therapeutic purposes in the case of tamponade and for diagnostic purposes if tuberculosis, bacterial infection, or malignancy is suspected. An IV fluid challenge may be a helpful temporizing measure in hypovolemic patients with tamponade.

Psychiatric Disorders

A significant number of patients with noncardiac chest pain suffer from panic disorder.³¹ In addition to chest pain, panic attacks can cause other symptoms that mimic MI, including diaphoresis, dyspnea, palpitations, and a sense of impending doom. A self-report of anxiety is a clue to the diagnosis of underlying panic disorder. Severe illness and its treatment with invasive procedures in the ICU can provoke profound psychological distress. The development of posttraumatic stress disorder is well described in ICU survivors, particularly in patients who experience episodes of extreme fear.³² Thus, while chest pain due to panic attack may not be acutely life threatening, this condition should not be considered benign and must be treated. Benzodiazepines are helpful in this regard. Psychiatric patients with cardiac or pulmonary disease can be especially challenging to diagnose, and a thorough, empathetic history is essential.

Herpes Zoster

Reactivation of the varicella-zoster virus from thoracic sensory ganglia causes a painful, dermatomal rash on the chest. The pain of shingles may precede the rash by several days, which can delay the diagnosis. The rash is characterized by vesicles that crust over after approximately 1 week. Oral acyclovir, valaciclovir, or famciclovir reduces the duration of herpetic neuralgia. Immunocompromised hosts are at high risk of complications from zoster infections and often require more aggressive treatment with IV acyclovir.

CONCLUSION

Attention to immediate life-threatening conditions and a thorough history and physical examination after initial stabilization are fundamental to managing chest pain in the ICU. A CXR, ECG, and serial cardiac enzymes should be ordered liberally but intelligently. A high index of suspicion for occult disease is necessary for complex ICU patients.

Gajic O, Urrutia LE, Sewani H, Schroeder DR, Cullinane DC, Peters SG. Acute abdomen in the medical intensive care unit. *Crit Care Med*. 2002;30(6):1187-1190.

In this retrospective study, delays in surgical evaluation and intervention were independent correlates of mortality. Risk factors for surgical delay included opioid use, mechanical ventilation, no peritoneal

signs, antibiotics, and altered mental state. A heightened index of suspicion for an acute abdomen is necessary in ICU patients with these risk factors.

Graber ML, Franklin N, Gordon R. Diagnostic error in internal medicine. *Arch Intern Med*. 2005; 165(13):1493-1499.

An analysis of 100 cases identified premature closure, that is, failing to consider alternatives once an initial diagnosis was made, as the most common cause of diagnostic error by internists. This study underscores the importance of not assuming that the admission diagnosis is necessarily correct or the only problem.

Hagan PG, Nienaber CA, Isselbacher EM, et al. The International Registry of Acute Aortic Dissection (IRAAD): new insights into an old disease. *JAMA*. 2000;283(7):897-903.

The IRAAD is composed of 12 international referral centers, from which 3 years of data and 464 patients were analyzed. A key finding was that what are considered classic presentations of aortic dissection such as tearing or ripping chest pain (50.6%), aortic regurgitation (31.6%), and pulse deficit (15.1%) were frequently absent, leading the authors to urge clinicians to maintain a high index of suspicion.

Han JH, Lindsell CJ, Storrow AB, et al. The role of cardiac risk factor burden in diagnosing acute coronary syndromes in the emergency department setting. *Ann Emerg Med*. 2007;49(2):145-152.

This post hoc analysis of more than 10,000 emergency department patients suspected of having ACS suggests that clinicians should not use cardiac risk factor burden to determine whether or not chest pain is cardiac in nature in patients older than 40. Interestingly, for patients younger than 40, the odds of ACS increased dramatically as the total number of cardiac risk factors increased.

Marvel MK, Epstein RM, Flowers K, Beckman HB. Soliciting the patient's agenda: have we improved? *JAMA*. 1999;281(3):283-287.

Although this study was conducted in primary care offices and not in an ICU, it emphasizes the importance of the basic history-taking process and listening to patients. It found that physicians interrupted their patients after a mean of only 23.1 seconds and that late-arising patient concerns were more common when physicians did not solicit questions during the interview.

The identification of myocardial injury is an important problem in the critical care setting. Biomarkers have been used to detect myocardial injury since 1954,¹ and since then, the sensitivity of serologic techniques has increased dramatically. While increased sensitivity has allowed clinicians to detect smaller amounts of myocardial necrosis, this has also posed several interpretive challenges. What constitutes significant myocardial damage? How should evidence of myocardial necrosis be interpreted in the absence of classical clinical criteria for myocardial infarction? In response to some of these challenges, a task force was formed to formulate a universal definition of myocardial infarction.² The task force developed a clinical classification of different types of myocardial infarctions (MIs), which was recently updated in 2012 (see Table 31-1).³ Of the five types, the most pertinent in the critical care setting are Type I (plaque rupture) and Type II (demand ischemia leading to infarction). These definitions rely on both electrocardiographic and biochemical information and stress that, in addition to biochemical findings, the diagnosis of MI requires symptoms or characteristic electrocardiogram (ECG) changes or findings from imaging, angiography, or autopsy.

ELECTROCARDIOGRAPHIC EVIDENCE

The acute coronary syndromes are classified by initial ECG findings, biochemical data, and clinical data. Patients are divided into three groups: those with ST elevation (STEMI); those without ST elevation but with enzyme evidence of myocardial damage (non-ST elevation MI or NSTEMI); and those with unstable angina (UA). Collectively, NSTEMI and UA are referred to as non-ST elevation acute coronary syndrome (non-STE-ACS). Classification according to a presenting ECG coincides with current treatment strategies since patients presenting with ST elevation benefit from immediate reperfusion.⁴ Accordingly, the American College of Cardiology/American Heart Association (ACC/AHA) guidelines recommend that patients with suspected ACS have an ECG obtained and interpreted within 10 minutes of presentation.⁵

Criteria for the diagnosis of STEMI include^{3,6}:

- New ST elevation at the J-point in at least two contiguous leads with the cut points
- 0.1 mV in all leads except V_{2-3} (for those leads cut points are as follows: ≥ 0.15 mV in V_{2-3} in women, ≥ 0.2 mV in V_{2-3} in men ≥ 40 , and ≥ 0.25 mV in V_{2-3} in men <40)
- New left bundle branch block
- New multilead ST depression with coexistent ST elevation in aVR
- New ST depression in ≥ 2 precordial leads (V_{1-4}) suggestive of a posterior MI

Many conditions can mimic STEMI and lead to false positives.³ An early repolarization pattern with up to 3-mm ST elevation in leads V_{1-3} can be seen in healthy individuals, typically in young men. Pre-excitation, bundle branch block, pericarditis, pulmonary embolism, subarachnoid hemorrhage, metabolic disturbances (e.g., hyperkalemia and hypothermia), and a left ventricular aneurysm can be associated with ST elevation in the absence of acute myocardial ischemia. On the other hand, some conditions can lead to false negatives, including prior myocardial infarction, paced rhythm, and LBBB when acute ischemia is not recognized. These pitfalls are common in the real world and large

clinical trials. When ECGs from the GUSTO IIB trial were reviewed by expert readers at a core lab, 15% of patients with STEMI were found to have been misclassified as NSTEMI, and these patients had a 21% higher mortality.⁷

“Nondiagnostic” ECGs are common in the setting of acute MI (AMI). In one study, 8% of patients who were subsequently determined to have ACS had a normal ECG, and an additional 35% had nonspecific changes.⁸ These nondiagnostic ECG findings may be due to an occlusion of only small vessels or an insensitivity of the 12-lead ECG to ischemia in the lateral or posterior left ventricular territory. Supplemental leads, such as V_{3-4R} and V_{7-9} , can be used to improve the detection of an MI of the free wall of the right ventricle and the inferior wall, respectively, increasing the sensitivity without decreasing specificity.⁹ An 80-lead body surface mapping system has also been shown to increase the sensitivity and specificity of ECG diagnosis of ischemia, but challenges with rapid application at the bedside remain.¹⁰ If ischemia is strongly suspected without ECG changes, serial ECGs or ECGs with additional leads should be performed.⁵ Serial ECGs have been shown to increase the sensitivity of MI detection from 55% to 68% compared to single ECGs.¹¹

ST segment depression on an ECG identifies patients with ACS at a high risk. In the Thrombolysis in Myocardial Infarction (TIMI) Risk Score, which has been shown to predict the likelihood of death and ischemic events, ST segment changes, along with advanced age and prior coronary artery disease, show the strongest association with severe coronary artery disease.¹²

T wave changes can also be prognostic, but the pretest probability of coronary artery disease must be taken into account. Large studies in asymptomatic patients demonstrate that most T wave changes are nonspecific. However, in the intensive care unit (ICU), some patterns are strongly associated with myocardial ischemia. Marked symmetric precordial T wave inversions (≥ 2 mm) suggest acute ischemia, usually due to a critical stenosis of the left anterior descending artery.¹³ In patients presenting to the emergency department with ACS, those with isolated T wave changes have a lower risk than those with ST depression but a higher risk than those with a normal ECG.¹⁴

CK-MB AND TROPONIN

With cardiac cell death, proteins are released into the blood, and detection of these proteins has played a key role in establishing the diagnosis of ACS, predicting its outcome, and directing treatment. Beginning early in the 1970s, creatine kinase (CK) and its isoenzyme MB (CK-MB) became the biomarkers of choice to establish myocardial injury and infarction. However, these biomarkers have been superseded by troponin T and I, parts of the troponin-tropomyosin complex in cardiac myocytes due to their increased sensitivity and specificity. Indeed, the current guidelines suggest that there is no benefit to checking CK-MB if contemporary troponin assays are available.⁵ Troponin elevations are highly specific for myocardial cellular injury, except for infrequent false positives due to fibrin interference or cross-reacting antibodies.¹⁵ Troponin is also much more sensitive than CK-MB as a result of its higher concentration in cardiac muscle and can detect even minor cardiac injury.¹⁵ Even minor increases in circulating troponin values correlate with adverse short-term and long-term outcomes.¹⁵ In non-STE-ACS, elevated troponins not only

TABLE 31-1

Clinical Classification of Different Types of Myocardial Infarctions

Type 1

Spontaneous myocardial infarction related to atherosclerotic plaque rupture, ulceration, fissuring, erosion, or dissection with resulting intraluminal thrombus in one or more of the coronary arteries leading to decreased myocardial blood flow or distal platelet emboli with ensuing myocyte necrosis

Type 2

In instances of myocardial injury with necrosis where a condition other than CAD contributes to an imbalance between myocardial oxygen supply and demand, e.g., coronary endothelial dysfunction, coronary artery spasm, coronary embolism, tachy-/bradyarrhythmias, anemia, respiratory failure, hypotension, and hypertension with or without LVH

Type 3

Cardiac death with symptoms is suggestive of myocardial ischemia and presumed new ischemic ECG changes or new left bundle branch block. However, death occurring before blood samples could be obtained or before cardiac biomarkers could rise, or in rare cases cardiac biomarkers were not collected

Type 4a

Myocardial infarction associated with percutaneous coronary intervention

Type 4b

Myocardial infarction associated with stent thrombosis as documented by angiography or at autopsy

Type 5

Myocardial infarction associated with coronary artery bypass grafting

Thygesene K, Alpert JS, Jaffe AS, et al. Third universal definition of myocardial infarction. *Circulation* 2012;126:2020-35.

predict increased risk but also identify the patients most likely to benefit from more aggressive antiplatelet strategies and an early invasive strategy with coronary angiography and revascularization when appropriate.⁵

The challenge for the clinician and particularly for the intensivist is that while the elevation of serum troponin is highly specific for myocardial cell damage, not all of the damage is a consequence of the rupture of an atherosclerotic plaque. Demand ischemia (Type II MI) can also lead to troponin release. Other causes of elevated troponin, many of which are common in the ICU, are listed in Table 31-2.³

This highlights the fact that MI should only be diagnosed in the appropriate clinical setting.³ Troponin release in critically ill patients may not always represent myocardial cell death. Endotoxin, cytokines, and other inflammatory mediators, along with catecholamines and conditions such as hypotension, inotropes, or hypoxia may cause the breakdown of cytoplasmic troponin into smaller fragments that can pass through endothelial monolayers and subsequently be detected by sensitive troponin assays.¹⁶ Although detectable troponin levels usually emanate from myocardial cells, they may not always represent either irreversible cell death or myocardial ischemia. Renal dysfunction is another factor associated with elevated troponin levels and both the sensitivity and specificity of this biomarker is decreased in this population.

Regardless of the cause, it is clear that the elevation of serum troponin levels is associated with a worsened outcome both in and out of the ICU, even after adjustment for severity of the disease.¹⁷ What is less clear is whether myocardial dysfunction represents the proximate cause of the worsened prognosis. It is often difficult to exclude ischemia in critically ill patients, but in a study of patients with septic shock, troponin predicted mortality even in patients in whom flow-limiting lesions were excluded either by stress echocardiography or at autopsy.¹⁸

These challenges are likely to be compounded by the greater use of high-sensitivity troponin (hs-cTn) assays. Compared to conventional

TABLE 31-2

Elevations of Cardiac Troponin Values Because of Myocardial Injury Not Due to Myocardial Ischemia

INJURY NOT RELATED TO MYOCARDIAL ISCHEMIA

Cardiac contusion, surgery, ablation, pacing, or defibrillator shocks

Rhabdomyolysis with cardiac involvement

Myocarditis

Cardiotoxic agents (e.g., anthracyclines and Herceptin)

MULTIFACTORIAL OR INDETERMINATE MYOCARDIAL INJURY

Heart failure

Stress (Takotsubo) cardiomyopathy

Severe pulmonary embolism or pulmonary hypertension

Sepsis and critically ill patients

Renal failure

Severe acute neurologic diseases (e.g., stroke or subarachnoid hemorrhage)

Infiltrative diseases (e.g., amyloidosis or sarcoidosis)

Strenuous exercise

Thygesene K, Alpert JS, Jaffe AS, et al. Third universal definition of myocardial infarction. *Circulation* 2012;126:2020-35.

assays, these assays have greater sensitivity (0.88 versus 0.75) and negative predictive value (0.96 versus 0.94).¹⁹ In one study, 62% of hospitalized internal medicine patients had an elevated level of hs-cTn, although only 6% of patients had a diagnosis of ACS. Accordingly, there is no consensus on how to use and interpret hs-cTn. Another challenge is that these assays are not yet standardized.²⁰

A further difficulty in the ICU is that patients may not experience classic symptoms of ischemia or may be unable to report them. Despite this potentially confounding factor, it is useful to the clinician to recall that an MI is diagnosed when sensitive and specific biomarkers are elevated in the right clinical setting.³ A characteristic rise and fall should be seen, as an initially elevated troponin may not result from ischemia.²¹ Troponin levels should be repeated to define the clinical course.

OTHER BIOMARKERS

While no biomarker has been shown to provide sensitivity or specificity for the diagnosis of MI superior to troponin, some biomarkers have been shown to provide information regarding prognosis.

Brain natriuretic peptide (BNP), and N-terminal pro-BNP (NT-proBNP) that is more stable are produced by the cleavage of the prohormone proBNP. ProBNP is released by the heart in response to stretching of the wall. The ischemic myocardium also releases BNP. Higher BNP levels in ACS patients correlate with an increased risk of subsequent death, and BNP appears to confer information independent of other clinical markers. Thus, in a study of 449 acute coronary syndrome patients, those with a high Global Registry of Acute Coronary Events (GRACE) Risk Score and high BNP were more likely to die than those with a high GRACE Risk Score and low BNP.²² Since women and older individuals have higher BNP levels, age- and gender-specific cutoffs may be needed.²³ Obese individuals have lower values, but renal dysfunction increases BNP levels, sometimes dramatically.²⁴⁻²⁵ BNP levels can also be increased in the setting of right ventricular strain, including patients with pulmonary embolism, in whom both elevated BNP and elevated troponin levels predict a worsened prognosis.²⁶ BNP remains a good indicator of ventricular dysfunction and myocardial wall stress, but what cutoff levels should be used in the ICU and what the clinician should do when the BNP exceeds those levels remains unclear.

C-reactive protein (CRP), an acute-phase reactant protein produced by hepatocytes, is a marker of inflammation shown to provide prognostic information in the setting of ACS. In GUSTO IV, CRP quartile correlated with a 30-day mortality in patients with ACS not undergoing revascularization, independent of troponin T.²⁷ Measuring CRP may be useful in the setting of ACS, but its value in a critical care setting may be limited to levels that can be elevated for reasons other than ACS.

MicroRNAs (mi-RNAs), short, noncoding RNAs that regulate gene expression at the post-transcriptional level, are novel markers that may prove clinically useful. In a recent meta-analysis, three mi-RNAs: 1) miR-133a; 2) miR-208b; and 3) miR-499 demonstrated high sensitivity and specificity for the ability to detect AMI.²⁸ However, the lack of a strong correlation among troponin-I, troponin-T, and high-sensitivity troponin-T and miR-499 in this study was concerning, as was significant heterogeneity among the patient groups.

Recent advances in ultrasound technology have allowed these devices to become smaller, more portable, and less expensive, so that this powerful imaging tool can be readily brought to the patient's bedside.¹ The concept of point-of-care (POC) ultrasound refers to the use of portable ultrasonography at the patient's bedside for diagnostic and therapeutic purposes.² POC ultrasound has rapidly proven to serve a vital role in the rapid assessment of cardiac, pulmonary, hemodynamic, vascular, neurologic, and gastrointestinal status. This chapter seeks to review the current use of POC ultrasound in the critical care setting. Specifically this chapter will discuss the following areas: (1) ultrasound physics and probe selection, (2) assessment of pulmonary status, (3) vascular access, and (4) additional topics. Chapter 33 provides a thorough discussion of echocardiography, including the echocardiographic assessment of intravascular volume status (preload responsiveness) and the use of echocardiography to diagnose shock and monitor the response to treatment. Training on these topics using a model-simulation-based educational curriculum has been shown to be effective and to positively impact patient care.³

ULTRASOUND PHYSICS AND PROBE SELECTION

Clinical ultrasound systems use transducers that emit and detect sound waves with a frequency between 2 and 27 MHz. Image production depends on the strength of the returning ultrasound signal and is directly related to the angle at which the beam strikes the acoustic interface. The ultrasound signal is described by its frequency and wavelength. A shorter wavelength (i.e., a higher frequency) provides better resolution but less penetration into tissues. Therefore, higher frequency probes (5 to 10 MHz) provide better resolution but are useful only for imaging superficial structures. Lower frequency probes (2 to 5 MHz) provide better penetration but have a lower resolution. Probe selection is based on matching the properties of the ultrasound probe with the particular structure that one is trying to image. Besides frequency, additional properties of the probe include the footprint (area emitting the ultrasound) and shape. Typical phased array probes emit at 3 to 5 MHz, have a small footprint, and produce a wide ultrasound image by sending out packets of ultrasound that are stitched together. Curved linear probes emit at 4 to 7 MHz, have a large footprint, and are ideal for imaging of abdominal structures. These probes generate a wide image because of the way the ultrasound waves are emitted. Linear probes emit at 10 to 27 MHz and are used for imaging superficial structures (Fig. 32-1).

Acoustic gel is used to minimize the difference in acoustic impedance from the probe to the skin. Standard 2D image creation is called B-mode (brightness mode). In this mode, there is a change in spot brightness for each ultrasound signal that is received by the transducer. M-mode (motion mode) is a graphic B-mode pattern that is a single screen line of ultrasound signal displayed over time and is used to assess the motion of structures along the ultrasound beam. Doppler ultrasound is a modality that is used to assess direction and intensity of flow by assessing the change in velocities secondary to the motion of the structure of interest (usually red blood cells). It is important to remember that Doppler signals are more accurate when the ultrasound signal is *parallel* to the direction of flow. With color Doppler, the Doppler echoes are displayed with colors corresponding to the direction of flow. With continuous wave Doppler, one assesses

the summation of velocities of flow along a line of the ultrasound signal. With pulse wave Doppler, one is able to assess flow velocity in an exact location but with the limitation of only being able to assess a range of velocities. From each transducer position, the target structure is focused on by three major movements: (1) *Tilt* refers to scanning left-to-right and is used to position structures in the middle of the screen, (2) *angle* refers to scanning superior-to-inferior, and (3) *rotation* refers to moving the probe in a clockwise or counterclockwise direction.

ASSESSMENT OF PULMONARY DISORDERS

Ultrasound assessment of pulmonary disorders offers tremendous value to the critical care physician. Ultrasound provides noninvasive, immediate bedside diagnosis, unlike a CT scan, which requires moving the patient. Ultrasound is especially useful in pregnant and pediatric patients where minimizing radiation exposure is important.

Performing an ultrasound for detection of pneumothorax is a simple, easily learned technique. Studies showed that inexperienced, recently trained personnel produced high detection rates for pneumothorax.^{4,5} Ultrasound of the lung relies on the physical principle that fluid collects in dependent areas, whereas gases collect superiorly. Therefore, positioning the patient appropriately for the exam is critical. In reporting the findings, the physician should specify both the patient's position (e.g., sitting, supine, right side down, or left side down) and the location of the probe. Probe placement should be posterior and inferior for detection of fluid but anterior and superior for detection of air. Although the probe can be placed transversely between two ribs, longitudinal placement with a view of the ribs is recommended because of the enhanced orientation provided by the rib shadows.

The curvilinear probe provides the best visualization of the pleural cavity. Although the lower frequency of 4 to 5 MHz does not allow the distinction of visceral from parietal pleura, it does yield visualization of lung sliding and air artifacts.

One of the initial steps in performing ultrasound of the lung is to visualize the diaphragm, which is a concave hyperechoic structure that descends with every breath. The liver on the right and the spleen on the left serve as landmarks during this initial visualization.

A subcostal or transdiaphragmatic abdominal approach can also be used to visualize the pleural cavity, but a potential difficulty of this view is that concave organs, such as the spleen, may reverberate, producing artifacts that appear to be dense lesions in the pleural cavity.

A normal ultrasound image of the lung will have the following features:

1. **Lung sliding:** As the lung inflates or deflates, the visceral pleura moves against the parietal pleura. The ultrasound images show this to and fro pleural movement, called lung sliding. Lung sliding is more prominent at the lung bases than the apex. It is absent in the presence of air (pneumothorax) or fluid (pleural effusion) in the pleural cavity. Inflammation leading to adherence of the two pleural membranes will also lead to absence of lung sliding. In the M-mode, lung sliding can be best seen with the muscle and parietal pleura represented as static horizontal lines above the to-and-fro movement of the visceral pleura and lung, which appears granular. This appearance on M-mode is called the *seashore sign* (Fig. 32-2).

FIGURE 32-1 ■ Ultrasound probe types.

FIGURE 32-2 ■ Seashore sign. M-mode ultrasound of normal lung.

2. A-Lines: These are motionless horizontal reverberations of the pleural lining that give a regularly spaced, hyperechoic artifact on the ultrasound image.
3. B-Lines: Also called *ultrasound lung comets*, B-lines probably represent the ultrasonic equivalent of radiologic Kerley B-lines. These artifacts have seven features: (1) a hydroaeric comet tail, (2) a hyperechoic signal, (3) well-defined on ultrasound, (4) arise from the pleural lining, (5) associated with disappearance of A-lines, (6) move with lung sliding when present, and (7) a pattern of indefinite spreading in a cephalad direction.⁶ B-lines are artifacts of water-thickened interlobular septa and indicate increasing amounts of extravascular pulmonary edema, such as occurs in congestive heart failure (Fig. 32-3).

Pleural Effusion

The pleural cavity is quite accessible to ultrasound visualization. Pleural effusions are best seen in dependent areas of the chest, that is, posterior or inferior areas. The fluid is bounded inferiorly by the diaphragm and peripherally by the visceral and parietal pleura. With respiration, the visceral pleural should move toward the parietal pleura, producing a sinusoid sign with M-mode, which is highly specific (97%) for the

FIGURE 32-3 ■ B-Line.

presence of a pleural effusion⁷ (Fig. 32-4). At times, the lung may appear to be floating in the pleural fluid. A positive sinusoid sign can detect the presence of a low-viscosity pleural effusion, but it may be falsely negative if the pleural fluid is very viscous.

Ultrasound is more sensitive and specific than either auscultation or chest x-ray and is therefore the method of choice to detect pleural effusions.^{8,9} Effusions over 1 cm thick are easily detected with an accuracy greater than 90%.⁹ Anterior presentation of an effusion suggests that it is abundant. When large effusions are present, deeper structures can be visualized, such as a consolidated lung or the mediastinal contents. A large effusion may reveal air artifacts in the lung and allow the examiner to differentiate consolidated from aerated lung.

With experience, the examiner can estimate the amount of effusion as mild, moderate, or large. The echogenicity of an exudate allows the examiner to make an educated guess as to whether it is a transudate or an exudate; all transudates are anechoic, whereas exudative effusions are usually echogenic.

Hemothorax and purulent pleurisy present similar ultrasound patterns. Hemothorax produces an echogenic signal, indicating numerous particles floating within the effusion. In rare cases, the entire pleural

FIGURE 32-4 ■ Sinusoid sign. The visceral pleura moves toward the parietal pleura with lung expansion, giving a sinusoidal sign on M-mode.

cavity might be hypoechoic, mirroring a whiteout seen on chest x-ray. CT will be helpful in these cases.

Ultrasound can facilitate thoracocentesis. The patient should be positioned in a sitting or lateral decubitus position. It is important that the patient remain in the same position throughout the localization of the lesion and the subsequent procedure. Before performing thoracocentesis, the operator should verify that the effusion is at least 1.5 cm thick and is visible over at least three intercostal spaces.⁷ The operator should identify the most dependent part of the pleural cavity and carefully insert the needle under direct (real-time) ultrasound visualization, making every effort to avoid accidental puncture of other structures during the process. Ultrasound-guided thoracocentesis is safe in mechanically ventilated patients.⁷ Following aspiration or biopsy, small pigtail catheters can be inserted and left in place for continuous drainage of the effusion.

Pulmonary Edema

Common practice in POC ultrasound of the lung parenchyma is the evaluation of B-lines. The number of B-lines correlates with the amount of extracellular lung water and the pulmonary wedge pressure ($P < 0.001$).⁶ Three or more B-lines in a single view are called B+ lines and represent interstitial edema.¹⁰ The presence of B-lines in a patient with acute dyspnea, evaluated together with measurement of circulating N-terminal pro b-type natriuretic peptide and the Framingham criteria, helps distinguish between cardiogenic and noncardiogenic pulmonary edema ($P < 0.001$).¹¹ The presence of 9 or more B-lines was found to be 100% specific for cardiogenic dyspnea.¹¹ Ultrasound can provide more than 90% sensitivity and specificity for the detection of acute cardiogenic pulmonary edema. Therefore, when combined with bedside echocardiography to evaluate cardiac function, the diagnosis of congestive heart failure can be confirmed before administering a diuretic.

Lung Consolidation

Lung consolidation is associated with air bronchograms and is visualized on ultrasound as lenticular air pockets within hypodense areas of consolidated lung.

Lung ultrasound has been found to be comparable to chest x-ray in making a diagnosis of pneumonia.^{12,13} The signal changes seen on ultrasound depend on the stage of the infection. Subpleural consolidation with a tree-like vascular pattern on Doppler might be present in the initial hepatization phase of lobar pneumonia. Lung sliding may be absent in the involved lobe secondary to inflammatory exudates. Later, during the resolution phase, ultrasound can detect

FIGURE 32-5 ■ Lung point in M-mode. Both the bar code and sea-shore signs are seen as the lung point moves across the image.

the appearance of B-lines, which appear secondary to increased aeration of the lung. Lung ultrasound can therefore be used to monitor the progression of pneumonia. There is a close correlation between the results of lung CT and ultrasound for evaluating re-aeration of the lungs.¹⁴

Pneumothorax

Ultrasound is highly accurate at detecting pneumothorax. The primary ultrasound feature is abolition of lung sliding, occasionally associated with A-lines and the absence of B-lines. In M-mode, this would give the appearance of multiple horizontal lines similar to a bar code. This nonspecific finding is seen in a number of other conditions, such as malignancy, chronic obstructive pulmonary disease (COPD), and pneumonia. More specific is the visualization of a lung point, that is, a point at which the lung and air can easily be visualized in the same M-mode image (Fig. 32-5). Moving the probe along the anterior, lateral, and posterior intercostal spaces and observation during an entire respiratory cycle at each point can help locate the lung point.

Chronic Obstructive Pulmonary Disease

Lung ultrasound in patients with COPD shows predominant A-lines with or without lung sliding but without a lung point. Ultrasound has an 89% sensitivity and 97% specificity for COPD.⁶

When using ultrasound to evaluate patients with dyspnea, first check for lung sliding and then for a lung point. The absence of lung sliding in association with the presence of a lung point indicates a diagnosis of pneumothorax. The presence of lung sliding with prominent B-lines ($>3/\text{field}$) indicates a diagnosis of pulmonary edema or pneumonia. The next steps are to check for the presence or absence of a dependent pleural effusion and evaluate for the presence or absence of lung consolidation. An exudative effusion, indicated by absence of a sinusoidal sign in association with lung consolidation, favors the diagnosis of pneumonia. Absence of prominent B-lines and predominance of A-lines indicate either a pulmonary embolism, worsening COPD, or pneumonia. Deep vein thrombosis (DVT) can be ruled out at this time by doing a venous exam of the lower and upper extremities. Absence of DVT and absence of any lung consolidation or pleural effusion favor the diagnosis of an exacerbation of COPD to explain the dyspnea. In patients with unclear or equivocal findings, further imaging modalities such as CT should be used.⁶

Lung ultrasound has some limitations. Central lung pathologies and areas under the ribs or scapula cannot be visualized. Examination of obese patients is difficult. Examination of trauma patients with subcutaneous emphysema is difficult or impossible.

Advanced Vascular Access

The use of ultrasound to aid in vascular access has advanced beyond its now widespread use for central venous access. Specifically, ultrasound has proven to reliably aid in the placement of difficult intravenous^{15,16} and intraarterial catheters.^{17,18} Use of ultrasound for peripheral venous access has been shown to significantly increase success rates as well.¹⁹ A recent meta-analysis was conducted to compare an ultrasound guidance technique for central venous access with an anatomic landmark technique and showed decreased risk of cannulation failure, arterial puncture, hematoma, and hemothorax with ultrasound.²⁰ However, it is important to emphasize that good anatomic knowledge and dynamic hand-eye-probe coordination to follow the needle tip are vital for success and avoidance of inadvertent arterial puncture.²¹ Use of ultrasound has resulted in complications related to injury of deeper structures (subclavian or vertebral artery) while inserting internal jugular central lines.²¹ This underlines the importance of formal training in ultrasound and simulated practice of central line placement, as supported by recently published guidelines.²¹

■ ADDITIONAL AREAS OF ASSESSMENT

POC ultrasonography is useful in assessing several other areas relevant to the issues faced by the critical care physician.

Deep Venous Thrombosis and Pulmonary Embolus

The current standard for evaluation of patients suspected to have DVT or pulmonary embolus involves CT pulmonary angiography and lower extremity compression ultrasonography. These tests are often performed despite a low pretest probability, and obtaining them potentially delays diagnosis.²² A recent study in patients with a moderate to high probability of pulmonary embolus evaluated multiorgan ultrasound, performed by intensivists, involving lung ultrasonography to search for subpleural infarcts, transthoracic echocardiography to detect right ventricular dilatation, and leg vein ultrasonography to detect DVT. The study showed that multiorgan ultrasound had a high sensitivity (90%) and specificity (86.2%) for detection of pulmonary embolus.²⁴

Airway Management

1. Endotracheal tube placement

A recent study has shown the utility of ultrasound for verification of successful endotracheal intubation, reporting a sensitivity and

specificity of 100% for the detection of successful endotracheal intubation versus esophageal intubation.²⁵ A recent evaluation of POC ultrasound examination, which included assessment for tracheal dilation with endotracheal tube cuff inflation and bilateral pleural lung sliding, demonstrated a high degree of sensitivity (93%) and specificity (96%) to detect endobronchial versus tracheal intubation.²⁶

2. Emergency cricothyroidotomy

Surface landmarks for identification are often not reliable for the identification of the cricothyroid membrane, especially in obese and female patients.^{27,28} Bedside ultrasound is a reliable modality for rapid identification of the anatomy for emergency cricothyrotomy (Fig. 32-6).²⁹

3. Percutaneous tracheostomy placement

Ultrasound improved success in accessing the trachea with more than 90% correct placement with the first-pass attempt in a cadaveric study.³⁰ Real-time ultrasound has been used for percutaneous tracheostomies with improved accuracy for midline placement of the needle.^{31,32}

Gastric Volume Assessment

POC ultrasound has also been used to assess gastric content and volume.^{33,34} A grading system has been proposed based exclusively on qualitative sonographic assessment of the gastric antrum and has shown a strong correlation with predicted gastric volume (Fig. 32-7).³⁴ The presence of fluid in the antrum identified by ultrasound in both the supine and right lateral decubitus positions correlates with a large, clinically significant amount of gastric contents. This ability to detect gastric volume by POC ultrasonography may be useful in assessing aspiration risk.

Intracranial Pressure Estimation

POC ultrasonography has been shown to provide rapid assessment of elevated intracranial pressures (ICP) based on the measurement of the optic nerve sheath diameter. The optic nerve sheath is contiguous with the dura mater and has a trabeculated subarachnoid space through which cerebrospinal fluid circulates. The relationship between the optic nerve sheath diameter and ICP has been well established.^{35,36} The sensitivity of ultrasonography in detecting elevated ICP was 100% (95% confidence interval [CI] 68% to 100%), and specificity was 63% (95% CI 50% to 76%).³⁵ An optic nerve sheath diameter of greater than 5 mm at a point approximately 2 mm from the retina suggests elevated ICP (Fig. 32-8).

FIGURE 32-6 ■ Longitudinal ultrasound view of the trachea. Longitudinal midline-scan view of the neck shows the cricothyroid membrane in red. Green and dark blue represent the thyroid and the cricoid cartilages, respectively. The orange lining shows the air-tissue border between the trachea and air. The light blue represent the tracheal cartilages.

FIGURE 32-7 ■ Ultrasound of gastric antrum to assess gastric volume. **A**, Probe (curved linear) position for gastric antrum acquisition. **B**, Ultrasound image.

FIGURE 32-8 ■ Ultrasound of optic nerve sheath diameter. **A**, Probe (linear) position. **B**, Ultrasound image.

KEY POINTS

1. Ultrasound machines are becoming less expensive and more portable, resulting in wider bedside application during physical examination to aid in clinical decision making. For this reason POC ultrasound use and knowledge is becoming a basic clinical skill for the critical care physician.
2. Probe selection depends upon the organ to be examined. Deeper structures need a lower frequency probe, which allows better penetration.
3. Doppler signals are more accurate when ultrasound signals are parallel to the direction of flow. Pulse wave Doppler can assess the flow velocity in an exact location whereas continuous Doppler assesses for a summation of velocities along the line of ultrasound signal.
4. Lungs ultrasound allows comprehensive assessment of the pulmonary system, especially with detection of pneumothorax and pleural effusion with high sensitivities and specificity. Bedside

KEY POINTS—cont'd

- ultrasound-guided thoracocentesis is safe even in mechanically ventilated patients.
5. Successful and safe POC ultrasound use for vascular access involves excellent anatomic knowledge and dynamic hand-eye-probe coordination to follow the needle tip at all times to prevent inadvertent arterial punctures and other complications.
 6. Evaluation for pulmonary embolus by POC ultrasound involves a multiorgan examination including lung ultrasonography, echocardiography, and lower extremity assessment to detect DVT.
 7. POC ultrasound has high sensitivity and specificity for the detection of successful endotracheal intubation as well as identification of anatomical structures and landmarks for cricothyroidotomy and percutaneous bedside tracheostomy.
 8. Lately, POC ultrasound is increasingly being used for assessment of gastric volume and content, especially prior to intubation for assessing aspiration risk.

Over the past 60 years, echocardiography has undergone substantial developments to become one of the most common modalities in the field of cardiovascular imaging. Starting in the 1980s, technologic advancements and the recognition of its potential moved echocardiographic imaging quickly into the operating room, emergency room, and intensive care unit (ICU). Today, it is fully integrated into medical subspecialties, such as anesthesiology, emergency medicine, critical care, and others.¹⁻³

Several aspects differentiate critical care echocardiography from the comprehensive cardiology echocardiographic examination. Critical care echocardiography is focused on the immediate integration of diagnostic information into clinical management. In ICU patients, the interaction of heart and lung function and the presence of multiple medical interventions can make the interpretation of findings more complex. The ability to obtain adequate images can be limited. The hemodynamic profiles of patients tend to change continuously. Therefore, 24-hour access to echocardiography is important.

Indications, Contraindications, and Safety

Indications for echocardiography, including the critical care and perioperative settings, are well established in the literature.⁴⁻⁷ While applications for echocardiography in the ICU continue to expand, the main indication remains the evaluation of hemodynamic instability and guidance of its clinical management (Table 33-1). Transthoracic echocardiography (TTE) represents the standard modality in the ICU, as it is noninvasive, readily available, and easy to use. While TTE presents minimal risk to patients, acquiring satisfactory images is often problematic. In particular, surgical dressings, obesity, chronic obstructive pulmonary disease (COPD), and the requirement for mechanical ventilation can make imaging difficult. Problems associated with obtaining satisfactory images using TTE are the most common indication for transesophageal echocardiography (TEE) in the critical care setting, especially when patients are already intubated and sedated. Other less frequent indications are the need to diagnose cardiac valvular pathologies, endocarditis, or intracardiac thrombi, or shunts. TEE requires advanced expertise and is an invasive procedure. As it carries increased risks of complications, absolute and relative contraindications are defined (Table 33-2), and risks and benefits must be considered prior to performing TEE.

Impact of Echocardiography in the ICU

Echocardiography is a valuable tool to identify the etiology of hemodynamic instability and to guide clinical management in a critical care setting.^{8,9} Although some results support the view that echocardiography can impact the management of ICU patients,¹⁰⁻¹² data regarding the impact of echocardiography on clinical outcomes remain sparse.^{13,14} One small study showed that using TEE to diagnose nonventricular pathologies as the etiology of hypotension was associated with improved ICU survival.¹⁵ In a study of 220 ICU patients, Kanji et al. showed that therapy in subacute shock guided by limited TTE was associated with an improved 28-day survival and reduced the

incidence of acute kidney injury (AKI) requiring renal replacement therapy (RRT).¹⁶

Training and Accreditation

While guidelines for training and accreditation for comprehensive echocardiography by cardiologists are well defined, similar guidelines are still evolving concerning the use of focused echocardiography by noncardiologists. Since about 2005, professional societies all over the world have been developing specific pathways and recommendations for training and accreditation requirements for focused critical care ultrasound. The first document on training and accreditation of echocardiography in intensive care developed by an international group of experts was published by the World Interactive Network Focused on Critical Ultrasound (WINFOCUS) in 2008.¹⁷ In 2009, a working group formed by the American College of Chest Physicians and La Société de Réanimation de Langue Française published a consensus statement about competency for performing critical care ultrasonography.¹⁸ Subsequently, an international expert group led by the European Society of Intensive Care Medicine proposed training guidelines and standardization of competency assessment for critical care ultrasonography including echocardiography.¹⁹ The same group published a consensus statement on the standards for advanced echocardiography in the ICU in 2014.²⁰

Billing

With the growing use of point-of-care (POC) echocardiography in the ICU, the question of reimbursement has been a topic of ongoing discussion. Several components of the focused critical care echocardiographic examination differ from the classic comprehensive echocardiographic examination. Physicians not fully accredited in echocardiography often perform the focused echocardiographic exam in critically ill patients, and the liability of interpretation only extends to the specific focus of the assessment. Images commonly are not stored for further clinical use. In the United States, Medicare uses the Current Procedural Terminology (CPT) code for the reimbursement of medical, surgical, and diagnostic services. Currently, the CPT coding does not incorporate an individual code for focused critical care ultrasound examinations, and its components do not fulfill the requirements of the standard diagnostic TTE exams or the limited/follow-up exam, as described in their coding system. TEE requires specific competence and is performed by physicians with advanced training. When performed in the ICU, these exams are commonly accepted using existing CPT codes for TEE examinations.

POC echocardiography has the potential to reduce overall ICU costs considerably. By adding a noninvasive, less expensive diagnostic and monitoring technology, it can expedite and focus clinical management and decrease the risk to patients significantly. With standardization of critical care echocardiography training, its differentiation from the classic comprehensive training, and the increasing evidence of the benefits of POC echocardiography, a specific billing code for the focused exam is warranted.²¹⁻²³

TABLE 33-1 Indications for Echocardiography in the ICU

- Circulatory failure (hypotension, shock)
- Sepsis
- Low cardiac output state
- Cardiac arrest
- ACS
- Pulmonary embolism
- Suspected cardiac etiology of respiratory failure
- Aortic dissection
- Cardiac trauma
- Endocarditis
- Suspected cardiac etiology of systemic embolism
- Cardiac evaluation for potential organ donation
- Guidance and assessment of circulatory assist devices (TVPM, IABP, ECMO, VAD)

ACS, acute coronary syndrome; ECMO, extracorporeal membrane oxygenator; IABP, intraaortic balloon pump; TVPM, transvenous pacemaker; VAD, ventricular assist device.

TABLE 33-2 Indications and Contraindications for TEE in the ICU

| INDICATIONS | CONTRAINDICATIONS |
|--|---|
| <ul style="list-style-type: none"> • Poor image quality in acute hemodynamic instability • Poor image quality second to severe obesity, emphysema, surgical drains/dressing • Comprehensive assessment of aortic dissection, endocarditis, valvular pathologies, prosthetic valves, intracardiac thrombus • Assessment of circulatory assist devices • Assessment of intracardiac shunt | <p>ABSOLUTE:</p> <ul style="list-style-type: none"> • Perforated viscus • Esophageal pathology (stricture, tumor, trauma, diverticulum, varices) • Recent esophageal or gastric surgery, s/p esophagectomy or esophagogastrostomy • Active upper GIB • Cervical spine injury <p>RELATIVE:</p> <ul style="list-style-type: none"> • Recent upper GIB • PUD • Coagulopathy, thrombocytopenia • Hiatal hernia |

TEE is mandatory for the comprehensive assessment of certain cardiac pathologies. In hemodynamic instability, when TTE imaging results in insufficient image quality, the intensivist has to weigh risk and benefits of performing invasive TEE exam. GIB, gastrointestinal bleed; PUD, peptic ulcer disease.

BASICS

Equipment

Typically, echocardiography equipment used in echocardiography laboratories and cardiac operating rooms features the newest and most advanced technologies. The most advanced equipment is not needed for use in a critical care setting. Several companies now offer machines with specific features geared toward use in emergency departments, trauma bays, or ICUs. These machines are used for the broad spectrum of critical care applications, including lung, vascular, and abdominal ultrasonography. The machines can be equipped with multiple software programs, including those useful for TTE and TEE. The ideal ICU ultrasound system is compact, portable, and durable. It requires minimal start-up time and has an easy-to-use operator interface. For routine daily use, it should have an extended battery life and internal storage capacity.

The transducers used for TTE and TEE examinations are typically phased-array transducers. They provide a frequency ranging from 1-10 MHz, which offers the optimal balance of penetration and resolution required to image the heart.

Knobology

Echocardiography machines have a collection of knobs and buttons to adjust image quality, utilize different modalities, and store images. As each manufacturer has a set arrangement of knobs and sliders and buttons, it is essential for each operator to become familiar with the layout of the machine that he or she will use on a regular basis. The most important controls and their function are as follows:

GAIN: Adjusts overall image brightness

TIME-GAIN-COMPENSATION (TGC): Selectively adjusts sector image brightness

DEPTH: Adjusts depth of view

ZOOM: Selects specific image sector

FOCUS: Adjusts focal zone

DYNAMIC RANGE: Adjusts grey-scale to filter out background noise

Ultrasound Modalities

More so than during the examination of anatomic structures other than the heart, the use of multiple ultrasound modalities is essential for echocardiography. The most commonly used modalities in the ICU are two-dimensional (2D) imaging, motion mode (M-mode), color flow Doppler (CFD), pulsed wave Doppler (PWD), and continuous wave Doppler (CWD). 2D remains the initial and most commonly used mode of anatomic imaging and qualitative assessment of gross pathologies in the ICU. A modality less frequently used is M-mode. M-Mode represents a one-dimensional image against time and has the advantage of excellent temporal resolution, which is useful for the imaging of fast moving structures like valvular leaflets.

When assessing hemodynamic profiles, the use of Doppler echocardiography, in addition to classic 2D imaging, provides the information needed for quantitative measurements. CFD displays blood flow velocity and direction of flow by color mapping. It combines qualitative 2D imaging with semiquantitative information about blood flow. CFD is useful for diagnosing intracardiac shunts or valvular pathologies, as well as seeking evidence of obstructions to blood flow. When a quantitative assessment is needed for the calculation of stroke volume (SV), cardiac output (CO), and pulmonary artery pressures (PAP), PWD and CWD are the modalities of choice. Both modes provide information about blood flow direction and numeric estimates of blood flow velocity at the interrogated anatomic site. Whereas PWD measures blood flow velocity at the specific site of the sample volume and is limited by a certain velocity threshold called the Nyquist limit, CWD displays the maximum velocity along the whole interrogation beam without a velocity threshold. Both modalities require alignment of the interrogation beam with the direction of blood flow to minimize the underestimation of velocity due to a suboptimal incidence angle. As with 2D imaging, several interventions can be applied to enhance Doppler quality and prevent artifacts due to the Nyquist limit. Most importantly, adjustment of the transducer location and frequency, sample volume depth, and movement of the baseline can maximize peak velocities with PWD.^{24,25}

STANDARD VIEWS AND ANATOMY

When performing echocardiographic examinations, the position of the transducer in relationship to the body is called the *acoustic window*, and the image plane is defined as the *view*. Image planes are in reference to the point of focus, which most commonly is the left ventricle (LV).

Image Acquisition and Optimization

Following a consistent order of image acquisition minimizes the risk of missing images and pathologies, and facilitates learning. Clockwise positioning and rotation of the transducer provides a simple and logical approach to the focused exam (Fig. 33-1).

FIGURE 33-1 ■ TTE transducer position and imaging windows. Starting with the PSLAX and the probe marker toward 11 o'clock, the clockwise movement and rotation of the transducer will provide a systematic approach to obtaining acoustic windows and imaging views. Rotation of the transducer from the PSLAX view by 90 degrees clockwise will show the PSSAX view. In the PSSAX view, tilting the transducer cephalad or caudad will visualize the short axis of the AV, LV midpapillary, and LV apical. Further rotation of the transducer from 1 o'clock to 3 o'clock and movement to the apical position visualizes the A4CH view. Flattening of the transducer will show the LVOT and A5CH views. Counterclockwise rotation in the apical view will show the A2CH and A3CH views. Maintaining the probe marker in the 3 o'clock position visualizes the SC4CH view in the SC position. The slight rightward angle of the transducer provides the LAX of the IVC. A2CH, apical two chamber; A3CH, apical three chamber; A4CH, apical four chamber; A5CH, apical five chamber; AV, aortic valve; IVC, inferior vena cava; LAX, long axis; LV, left ventricle; LVOT, left ventricular outflow tract; PSLAX, parasternal long axis; PSSAX, parasternal short axis.

Whether with TTE or TEE, standardized views are based on anatomic landmarks, which can be obtained at defined acoustic windows with specific transducer positions and angles. To avoid inadequate imaging and the risk of misinterpretation, knowledge of the specific anatomic landmarks defining each view is pertinent. In addition, the following techniques should always be used to optimize imaging. *Body position:* Extension of the left arm opens up the parasternal windows while a slight left-side tilt can bring the cardiac apex closer to the chest wall. Flexing the legs at the hip facilitates the acquisition of subcostal windows. *Image acquisition:* Small changes in transducer position and angle, a change in intercostal space above or below, and

the use of TEE can provide improved imaging. *Machine setting:* Aside from adjusting gain, TGC, and dynamic range, precisely adjusting the focus and depth to the region of interest (ROI) is critical. In addition, using the zoom feature can also be helpful. Especially in Doppler modes, these adjustments can improve measurements and avoid Doppler aliasing. Another option for improving image quality is contrasted echocardiography.²⁶ Even though not commonly utilized by intensivists when performing focused ICU exams, injection of contrast media can significantly enhance opacification of the right and left ventricular chambers and enhanced the definition of the endocardial border.

Transthoracic Echocardiography

In TTE, three standard acoustic windows are used: the parasternal, apical, and subcostal positions (Fig. 33-1). A fourth position called suprasternal is additionally used during comprehensive exams and in the pediatric population.

Standard Transthoracic Views

The focused echocardiographic exam in the ICU commonly includes five major views: (1) the parasternal long-axis (PS LAX); (2) the parasternal short-axis (PS SAX); (3) the apical four-chamber (A4CH); (4) apical five-chamber (A5CH); and (5) the subcostal long-axis (SC LAX) (Table 33-3).^{17,20}

PS LAX is obtained by positioning the transducer in the left third or fourth intercostal space (ICS), along the anterior midclavicular line, with the transducer marker directed toward the right shoulder (Fig. 33-1). This view is primarily used to evaluate LV and right ventricle (RV) size and systolic function, as well as to obtain quantitative measurements of ventricular size and wall thickness by the M-mode. The mitral valve (MV) and aortic valve (AV), including the left-ventricular outflow tract (LVOT) and aortic root, can be assessed with 2D and CFD for regurgitation, stenosis, or dynamic outflow obstruction. Additionally, this view can be used for the visualization of pericardial pathologies.

PARASTERNAL SHORT-AXIS VIEWS are obtained in the same transducer position as the parasternal long-axis view, with the transducer rotated 90° clockwise and the marker directed toward the left shoulder (Fig. 33-1). Within this view, multiple planes of the heart can be imaged depending on the tilt of the transducer. When tilting the probe from superiorly to inferiorly, visualization starting with the short axis of the AV over the basal and mid-SAX of the LV down to the apical segment of the LV is possible. This view is best used for the evaluation of LV size and systolic function. It is optimal for describing regional wall motion abnormalities, as all territories of coronary perfusion can be visualized simultaneously. In addition, the basal AV SAX view can provide information about the tricuspid valve (TV), including measurements of right ventricular systolic pressure (RVSP) by CWD.

APICAL VIEWS provide images of all four chambers (Fig. 33-1). Most commonly used in the ICU are the A4CH and A5CH views. With the transducer positioned at the apex of the heart, commonly in the 6th or 7th ICS along the anterior axillary line, the probe marker is directed toward the left axilla. With tilting of the probe superiorly, the 4CH and 5CH views are obtained.

The 4CH view is utilized for the assessment of atrial and ventricular chamber sizes, biventricular systolic function, and regional wall motion abnormalities. Due to the optimal incidence angle and visualization of the TV, MV, and AV in the 4CH and 5CH views, quantitative measures by M-mode, CFD, CWD, and PWD are best obtained from the apical position. These views are mostly used by intensivists for quantitative evaluation of RV function and RVSP, LV cardiac output and diastolic function, as well as the evaluation of valvular pathologies by spectral-Doppler echocardiography.

From the 4CH position, a counterclockwise rotation of the transducer by 90° and 110° will visualize the apical two-chamber (A2CH) and three-chamber views (A3CH), which completes the visualization of all left-ventricular wall segments when combined with the 4CH view.

SUBCOSTAL VIEWS are obtained by positioning the transducer in the subxiphoid or subcostal position while maintaining the marker directed toward the left lateral side of the patient. Aiming the probe toward the left shoulder and maintaining it flat on the abdomen, the heart is cut in a horizontal plane, showing all four chambers and particularly the RV free wall (Fig. 33-1). A 90° rotation of the transducer counterclockwise while slightly aiming the probe toward the right shoulder will visualize the inferior vena cava (IVC) and its junction into the RA. These views can provide information about pericardial pathologies, such as pericardial effusion and tamponade. When angled slightly toward the right and caudad, global volume status can be assessed by measuring IVC diameter and dynamic collapse with respiratory variation (Fig. 33-1).

Transesophageal Echocardiography

In the past, the use of TEE in a critical care setting was restricted by availability, technical issues, and need the for operator expertise. With improvements in equipment and growing expertise among intensivists, the use of this modality is increasing. Superior image quality and the ability to evaluate for certain pathologies remain the advantages of TEE over TTE.

Safety of Transesophageal Echocardiography

TEE in ambulatory and nonoperative settings has an incidence of adverse events of between 0.2% and 0.5% and a mortality rate of <0.01%.²⁷ TEE in the ICU has slightly higher morbidity and mortality. Multiple studies show that the incidence of adverse events ranges from 1.6% to 5%.^{15,28-30} In a recent review of 20 studies, Huettemann

TABLE 33-3 Standard TTE Views, Anatomic Structures Seen, and Their Common Use

| STANDARD TTE VIEWS | STRUCTURES | COMMON ASSESSMENT |
|--------------------|-----------------------------------|--|
| PS LAX | LA, LV, RV, MV, AV, LVOT, Desc Ao | LV and RV size, LV and RV systolic function, RWMA, AV and MV pathologies, LVOT obstructions (SAM), pericardial effusion/clot/tamponade, pleural effusion, LVOT diameter for SV calculation, aortic dissection and aneurysm |
| PS SAX AV | LA, RA, RV, PA, AV, TV, PV | AV pathologies, RV size and systolic function, TV pathologies, RVSP, intracardiac shunts, catheters/PM leads/cannulas |
| *PS SAX MID-PAP | LV, RV | LV size and systolic function, RWMA, pericardial effusion/clot/tamponade |
| *A4CH | LA, RA, LV, RV, MV, TV | LV and RV size, LV and RV systolic function, RWMA, LA and RA size, MV and TV pathologies, RVSP, TAPSE |
| A5CH | LA, RA, LV, RV, LVOT, AV, MV | LVOT obstructions (SAM), VTI LVOT and AV, AV pathologies |
| A2CH | LA, LV, MV | RWMA, MV pathologies |
| *SC SAX | RA, LA, RV, LV, diaphragm | Pericardial effusion/clot/tamponade, RV size and systolic function, RA size, catheters/PM-leads/cannulas |
| *SC IVC LAX | IVC | Volume status, pericardial effusion/clot/tamponade |
| SC IVC SAX | IVC, Desc Ao | Volume status, pericardial effusion/clot/tamponade, aortic dissection and aneurysm, IABP |

As seen, the PS SAX, A4CH, and SC SAX in combination provide most information needed in the acute situation. Additional views for hemodynamic assessment are added to show the most common views used in the ICU. 2CH, two chamber; 4CH, four chamber; 5CH, five chamber; A, apical; AV, aortic valve; Desc Ao, descending aorta; IABP, intraaortic balloon pump; IVC, inferior vena cava; LA, left atrium; LAX, long axis; LV, left ventricle; LVOT, left ventricular outflow tract; MV, mitral valve; PM, pacemaker; PS, parasternal; RA, right atrium; RV, right ventricle; RWMA, regional wall motion abnormalities; SAM, systolic anterior mitral valve leaflet motion; SAX, short axis; SC, subcostal; TV, tricuspid valve; VTI, velocity-time interval.

et al. reported that the incidence of TEE-related complications in the ICU was 2.6%; there were no TEE-related deaths.^{27,31} The main complications associated with TEE are arrhythmias, hypotension, airway compromise, and bleeding. These complications are more likely to occur in critically ill patients as compared to relatively healthier subjects because ICU patients often are hemodynamically unstable or already prone to hemorrhage. Nevertheless, if the operator is cognizant of the potential complications and takes pains to weigh the risks versus the benefits carefully, TEE can be performed safely in the ICU. Preparation of the patient before TEE is important. First, the indications for and specific questions to be answered by the exam have to be defined. Second, potential contraindications to TEE, such as recent esophageal or gastric surgery or active upper gastrointestinal bleeding, must be ruled out. Third, coagulation status must be assessed, and abnormalities corrected, if possible. Fourth, nil per os (NPO) status must be assured. Fifth, the mode of sedation, the need for administration of paralytic agents, and airway protection have to be addressed. When performing the exam, insertion and manipulation of the probe should be tailored to the patient's condition and coexisting risk factors.

Standard Transesophageal Views

The TEE exam in the perioperative setting includes twenty standard views.³² TEE in the ICU rarely requires a comprehensive exam. Several different protocols have been proposed for the focused TEE exam in critically ill patients, emergency room patients, or acute intraoperative emergencies.^{33,34} The goal of the focused exam remains the same as with TTE, and unless prohibited by the severity of situation, acquisition of standardized views should be obtained.

Although a comprehensive TEE exam utilizes views at four levels of the esophagogastric tract, the two main depths used during the focused exam are the midesophageal and transgastric planes. The midesophageal level provides optimal views for specific anatomic evaluation of cardiac structures, as the transducer is near the heart. Transgastric views are mainly used for quick evaluations of LV size, systolic function, and wall motion abnormalities. In addition, spectral-Doppler of the AV is performed in the deep transgastric view, as the incidence alignment angle is best in this location. The transgastric view can also show loculated or dependent pericardial effusions, which may be difficult to see in the midesophageal views.

HEMODYNAMIC ASSESSMENT

Echocardiography represents a method for the immediate diagnosis, management, and monitoring of hemodynamic profiles in critically ill patients. With an examination that rarely takes more than a few minutes to complete, echocardiography can provide the intensivist with anatomic information about the critically ill patient's intravascular volume status, the presence or absence of various forms of cardiac pathologies (e.g., pericardial effusion and tamponade; regional wall motion abnormalities), myocardial contractility, and ventricular dimensions. For the subsequent interpretation and use of this information, it is pertinent to incorporate the influence of concurrent pathologies and medical treatments on echocardiography findings. Especially common factors, such as arrhythmias, vasopressor or inotropic support, and mechanical ventilation, need to be considered during the qualitative and quantitative hemodynamic assessment.

Cardiac Preload and Volume Responsiveness

As the management of the critically ill patient has evolved, the question of volume (i.e., preload) responsiveness has taken priority over static parameters like central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP).⁹ Many experts are skeptical about the clinical utility of static pressures for guiding the hemodynamic management of critically ill patients. Neither CVP nor PAOP is a good predictor of preload responsiveness (i.e., an increase in cardiac output

or stroke volume after bolus administration of intravenous crystalloid or colloid solutions). With the validation of echocardiography, bedside examination is increasingly replacing invasive monitoring in the contemporary evaluation of cardiac preload and prediction of volume responsiveness.^{9,35} Assessment of IVC diameter and the collapsibility, cardiac chamber size, and ventricular outflow tract stroke volume (LVOT SV) measurements are the most common methods used for qualitative and quantitative evaluation of these parameters.³⁶

Assessment of IVC size and its dynamic variation during changes in intrathoracic pressure with mechanical ventilation is the most common way for using echocardiography to evaluate cardiac preload and volume responsiveness in ICU patients. The average diameter of the IVC is 17 mm. The absolute IVC diameter by itself, unless <10 mm or >20 mm, does not correlate well with right atrial pressure (RAP) or preload responsiveness.³⁷ However, dynamic changes in the IVC diameter due to respiration can provide information about preload responsiveness.^{36,38} Barbier et al. showed that dynamic changes in IVC diameter of >18% predict fluid responsiveness with a sensitivity and specificity of 90% to 93%.³⁹ Feissel et al. confirmed these findings with a slightly different index of IVC collapsibility, showing a sensitivity and specificity of 90% to 92%, respectively.³⁷ At the subcostal acoustic window, optimal measurements of the IVC diameter are made using the M-mode in the short-axis view. When interpreting information derived from IVC diameter measurements, it is important to incorporate the effects of atrial arrhythmias, significant tricuspid regurgitation, atrial shunting, or increased intraabdominal pressure on the appearance of the IVC.

Imaging of cardiac chamber size is routinely used in conjunction with other measurements to assess qualitatively intravascular volume status. Most common measurements are LV end-diastolic diameter (LVEDD) and the left ventricular end-diastolic area (LVEDA) utilizing the SAX view of the LV (Fig. 33-2). Attention should be paid to poor image quality and foreshortening of the chamber, as these worsen endocardial border definition and lead to false calculations. Although the measurement of LVEDA provides a reliable estimation of left-ventricular volume in most patients,⁴⁰ low LVEDA does not necessarily indicate systemic hypovolemia; other causes of low LV preload must be considered. Other potential causes of impaired LV diastolic filling include loss of atrial contraction due to arrhythmias, right ventricular dysfunction, and mitral valve dysfunction. Apart from situations of severe hypovolemia,^{41,42} quantitative measurements of left or right ventricular chamber size have not been shown to correlate reliably with cardiac preload and volume responsiveness.⁴³ Dynamic changes in LVEDA, however, correlate with volume responsiveness.⁴⁴

Stroke Volume and Cardiac Output

Left-ventricular stroke volume (LV SV) and cardiac output (CO) can be calculated using echocardiography.^{45,46} Whereas CO measured by thermodilution is a reflection of right-sided CO, measurements with echocardiography utilize left-sided inflow and outflow at the level of the mitral valve (MV), LVOT, and aortic valve (AV). In addition, newer noninvasive modalities are based on PWD of aortic blood flow to assess cardiac output.³¹ While all of these anatomic locations have been validated in the literature, calculations using LVOT and AV are the most accurate when compared to the thermodilution method.^{45,47} The continuity equation is used to calculate LV stroke volume by measuring LVOT diameter and LVOT VTI. Moreover, measurements by TTE are best obtained in the PS-LAX and A5CH views. Once LV SV is calculated, multiplication by the HR provides CO (Fig. 33-3). As LV SV is dependent on the LV preload, limitations affecting LV filling, as mentioned above, have to be considered when calculating SV and CO.⁴⁸

Right- and Left-Ventricular Afterload

With the ability to determine pressure gradients and flow in the heart by echocardiography, pulmonary vascular resistance (PVR) and

$$FS = [(EDD - ESD) / EDD] \times 100$$

$$FAC = [(EDA - ESA) / EDA] \times 100$$

Example:

$$FS_{LV} = [(6.0 - 4.5) / 6.0] \times 100$$

$$= 25 \%$$

$$FAC_{LV} = [(18.5 - 7.3) / 18.5] \times 100$$

$$= 60 \%$$

FIGURE 33-2 ■ Chamber size and semiquantitative calculation of left ventricular function.

Fractional shortening methods utilized LV end-diastolic and end-systolic diameter from PSLAX or PSSAX midpapillary to calculate percentage value. Normal FS values are 25%-45%, correlating to normal EF. Fractional-area-change values correlate directly with EF. Measurements of area are taken from PSSAX midpapillary view. EDA, end-diastolic area; EDD, end-diastolic diameter; ESA, end-systolic area; ESD, end-systolic diameter; FAC, fractional area change; FS, fractional shortening; PSLAX, parasternal long axis; PSSAX, parasternal short axis.

systemic vascular resistance (SVR) can be indirectly calculated using the following equation:

$$\text{Resistance} = \Delta P / CO$$

Based on this concept, several small studies have shown an adequate correlation using transvalvular gradients at the tricuspid valve (TV) and MV to calculate pulmonary and systemic vascular resistance. Clinically cumbersome and without broad validation in the literature, these methods are not used on a routine basis in the ICU. In clinical practice, qualitative aspects seen on echocardiography are used to assess SVR. Best seen in the LV SAX view, a hyperdynamic ventricle in the setting of normovolemia suggests a low SVR. From this view, measurement of LVEDD and visual estimation of LV contractility can be used for fast and easy qualitative SVR estimation.⁴⁹

For the assessment of PVR at the bedside, indirect calculation of PAP by TR jet when present is commonly achieved using the modified Bernoulli equation (Fig. 33-4). Measurement of peak TR_{vel} , when added to RAP, provides an estimate of RV systolic pressure (RVSP) that correlates well with SPAP in the absence of tricuspid or pulmonary valve pathology.

Left-Ventricular Systolic Function

Assessment of LV systolic function is one of the key elements of the ICU echocardiographic exam. Not only can an assessment of LV systolic function provide information about the etiology of circulatory or respiratory failure, but it also can be used to guide and monitor ensuing medical management. Multiple methods are available for the echocardiographic evaluation of LV function (Table 33-4). In an acute setting, the fastest and easiest assessment of myocardial function and

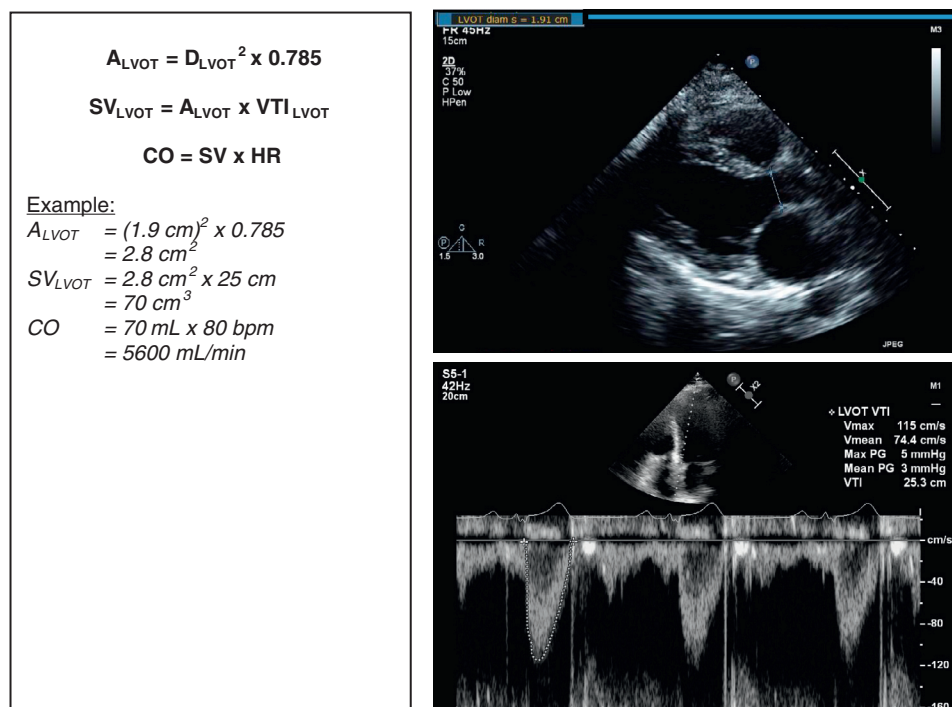

FIGURE 33-3 ■ LV SV and CO calculation. When LVOT diameter is measured in the PSLAX view, the LVOT area can be calculated. LVOT VTI is measured using PWD in the A5CH view. As seen above, in this example the LV SV is 70 mL. When multiplying with an HR of 80 bpm, a CO of 5.6L/min is estimated. A_{LVOT} , LVOT area; CO, cardiac output; D_{LVOT} , LVOT diameter; HR, heart rate; LVOT, left ventricular outflow tract; SV, stroke volume; VTI, velocity-time-integral.

$$RVSP = (TR_{PEAK})^2 + RAP$$

FIGURE 33-4 ■ RVSP measurement using the TR jet. After optimal alignment of the Doppler beam with the TR jet in the A4CH view, RVSP can be calculated by adding the square of the TR peak velocity in m/s to the RAP. When estimating an RAP of 10 mm Hg, RVSP in this example would be 23 mm Hg. RAP, right atrial pressure; RVSP, right ventricular systolic pressure; TR, tricuspid regurgitation; TR_{PEAK} , peak velocity of TR jet.

ejection fraction (EF) uses qualitative or semiquantitative methods. For the qualitative assessment, thickening of the myocardium and endocardial inward motion in the LV SAX view is used to estimate systolic function. Caution must be taken when the LV is small, or there is significant LV hypertrophy (LVH), as LV function appears different depending on the intracavitary size. A simplified classification scheme for LV function (i.e., hyperdynamic, normal, moderately depressed, or severely depressed) is usually sufficient in a critical care setting, and several authors have shown that little training is required to make this assessment reliably.^{50,51} When performed by an experienced

echocardiographer, estimates of LVEF correlate well with quantitative measurements.^{52,53}

Semiquantitative measurements can be obtained utilizing the LV SAX view by calculating fractional shortening (FS) or fractional area change (FAC) (Fig. 33-2). Since this view only visualizes one plane of the myocardium, additional qualitative assessments of the complete LV should be performed to avoid errors due to coexisting regional wall motion abnormalities (RWMA).

A more accurate (but more time-consuming) assessment of LV systolic function can be made by volumetric measurements.

Both the area-length formula and Simpson's method reliably estimate LVEF.⁵⁴

Right-Ventricular Systolic Function

Compared to the assessment of LV function, assessment of RV function is more complex as ventricular compliance, wall thickness, systolic function, and TV function are more closely linked.^{55,56} Significant RV systolic dysfunction often presents with RV dilation and TV regurgitation. Simultaneously, normal RV function can be observed with RV dilation and significant TV regurgitation when the RV has time to adjust to chronically increased afterload by wall hypertrophy. Additionally, the RV has a complex geometric structure, making volumetric measurements and imaging more difficult. For these reasons, an assessment of right ventricular function is currently done using a combination of qualitative and semiquantitative measures (Table 33-5). Image acquisition is best via utilizing the PS LAX and apical 4CH views. Semiquantitative measures only assess certain regions of the ventricle,

and caution must be taken not to extrapolate these findings. FAC is currently recommended for semiquantitative calculation of RVEF, as traditional 2D methods assume symmetry of the ventricular structure,^{57,58} and 3D methods are still being validated. Tricuspid annular plane systolic excursion (TAPSE) is easily obtained by TTE and is commonly used in combination with other methods (Fig. 33-5). RVSP, as described above, can reflect the ability of the RV to generate pressure and indirectly provides information about RV function. It is important to correlate measurements with factors that affect RV preload, pulmonary vascular resistance, and valvular function before making clinical judgments. Conditions that are commonly encountered in the ICU, such as adult respiratory distress syndrome (ARDS), pulmonary edema, volume overload, and arrhythmias, influence measured RVSP and often render them uninterpretable.

CIRCULATORY FAILURE

Systematic Approach to Circulatory Failure

Circulatory failure is one of the most common indications for echocardiography in the ICU.^{5,59} Several algorithms for hemodynamic assessment and management of circulatory failure by echocardiography have been described.⁶⁰⁻⁶² The algorithm should include the following steps: (1) seek to identify gross pathologies, such as cardiac tamponade, abnormal myocardial function, or marked hypo- or hypervolemia; (2) determine volume responsiveness and signs of low SVR; and (3) look for more subtle etiologies for hemodynamic instability like valvular pathologies (Fig. 33-6). Even though the clinical

TABLE 33-4 Methods for Assessment of the LV and RV

| LV ASSESSMENT | NORMAL VALUES | |
|------------------------------------|--------------------------------|--------------------------------|
| Assessment of LV size | male | female |
| *LV size (midpapillary diameter) | EDD: 40-60 mm ESD: 25-40 mm | EDD: 35-55 mm ESD: 20-35 mm |
| Assessment of LV systolic function | | |
| Qualitative | | |
| Semi-quantitative | | |
| *FS | 25%-45% | |
| *FAC | 35%-65% | |
| Quantitative | | |
| 2D volumetric EF | >55% | |
| 3D volumetric EF | >55% | |
| *LV wall thickness | <10 mm | |
| dP/dt | >1200 mm Hg/sec | |
| Assessment of MR | | |
| *Extent/quality of MR | | |

| RV ASSESSMENT | NORMAL VALUES |
|------------------------------------|---------------|
| Assessment of RV size | |
| *RV size (RV basal EDD) | >4.2 cm |
| *RV to LV ratio | >0.8 |
| Assessment of RV systolic function | |
| *Qualitative | |
| *FAC | 35%-65% |
| *TAPSE | >20 mm |
| *RV wall thickness | <5 mm |

Most commonly used methods in the ICU are marked with asterisks. EDD, end-diastolic diameter; EF, ejection fraction; ESD, end-systolic diameter; FAC, fractional area change; LV, left ventricle; MPI, myocardial performance index; MR, mitral regurgitation; S', velocity of RV free wall or TV annulus by PWD; TAPSE, tricuspid annular plane excursion.

TABLE 33-5 Echocardiographic Signs Suggestive of Pericardial Tamponade

PERICARDIAL TAMPONADE

- Effusion/clot on echo
- Dynamic collapse of RA +/- RV
- IVC plethora
- Exaggerated transvalvular flow patterns of tricuspid and mitral valve >25% with respiration
- Increase in interventricular dependence with respiration

Respiratory-induced pulsus paradoxus with exaggerated changes in flow >25% is seen in mitral or tricuspid valve Doppler flow. IVC, inferior vena cava; RA, right atrium; RV, right ventricle.

FIGURE 33-5 ■ Tricuspid Annular Plane Systolic Excursion (TAPSE). The distance of the tricuspid annulus from the apex is measured in the A4CH view. Subtraction of systolic from diastolic distance results in the TAPSE value. Normal values are greater than 20 mm.

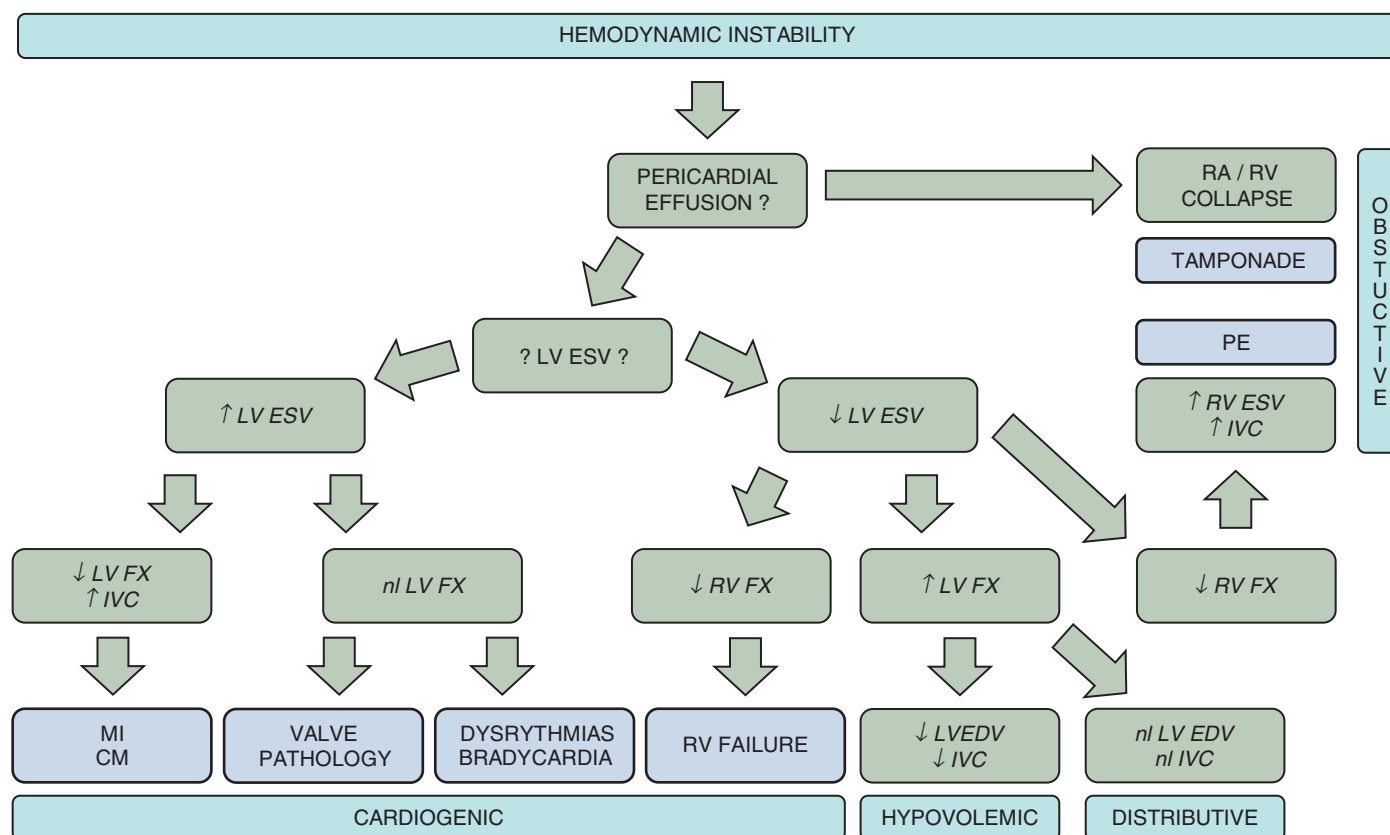

FIGURE 33-6 ■ Algorithm for the echocardiographic assessment of hemodynamic instability.

After initial 2D assessment for hemodynamic-compromising pericardial effusion, evaluation of LV and RV size in systole and diastole and LV and RV systolic function is performed. Differentiation in cardiogenic, distributive, hypovolemic, or obstructive etiology of shock is often possible by following this algorithm. CM, cardiomyopathy; EDV, end-diastolic volume; ESV, end-systolic volume; FX, systolic function; IVC, inferior vena cava; LV, left ventricle; MI, myocardial ischemia; nl, normal; RA, right atrium; RV, right ventricle; ↑, increased/hyperdynamic; ↓, decreased/depressed.

context will initially prompt evaluation for specific pathologies, it is important to perform a systematic assessment to avoid overlooking coexisting or complicating pathologies that need to be addressed or managed. When patients are being treated with inotropic agents or vasopressors, the echocardiographic findings must be interpreted in this context. The concurrent presence of different types of shock can complicate the hemodynamic assessment and the interpretation of echocardiographic findings. As myocardial function and SVR are pharmacologically altered, the underlying etiology for hemodynamic dysfunction may be obscured. Apparently normal ventricular function in the setting of sepsis can be observed with concomitant myocardial depression. Moreover, hyperdynamic ventricular function can be seen in both sepsis and hypovolemia. Therefore, it is essential to correlate echocardiographic findings with the overall clinical picture. Table 33-6 shows the integration of echocardiographic findings and invasively measured values in different states of shock.

When monitoring clinical management, serial imaging must be performed and findings compared with previous ones. Additionally, management should be correlated to the overall picture as not every patient with a certain hemodynamic disorder benefits from the same specific treatment.

Hypovolemic Shock

Hypovolemic shock is the result of an absolute or relative decrease in circulating volume secondary to volume loss or maldistribution.

Echocardiography can identify intravascular hypovolemia and volume responsiveness using several approaches.⁹ As described above, the most commonly used modalities are the evaluation of the IVC, LV EDD or EDA, and variation in LV SV (Fig. 33-7). An IVC diameter of <10 mm and significant changes in the IVC diameter with positive pressure ventilation reflect systemic hypovolemia and suggest volume responsiveness.^{37,39} If the EDD is <25 mm with hyperdynamic LV systolic function, and kissing papillary muscles are seen during systole, then significant LV hypovolemia is present (Video 33-1).⁴¹ Variations in LV SV reflected by changes in LVOT velocity predict the volume responsiveness. A change in LVOT V_{MAX} of >12% and a change in VTI_{LVOT} of >20% is seen in fluid responders.⁶³

Cardiogenic Shock

Left heart failure due to systolic dysfunction is associated with low LVEF, low CO, commonly systemic volume overload, and signs of pulmonary and hepatic congestion. Echocardiography can evaluate pathognomonic findings for heart failure and cardiogenic shock, as well as possibly provide insights regarding etiology. Global myocardial dysfunction causing cardiogenic shock can be recognized when combining qualitative with supporting echocardiographic and clinical findings. Strong indicators for cardiogenic etiology of shock include enlarged LV size, qualitatively depressed LV function, FS <25%, low EF by FAC, and low CO by LVOT Doppler measurements.⁶⁴

TABLE 33-6 Echocardiographic and Hemodynamic Profiles in Different Shock States

| TYPE OF SHOCK | ECHO | | | | | INVASIVE MONITORING | | | |
|-----------------------|------------------|-------|--------|--------|---------------------------------|---------------------|-----|---------|------------------|
| | CARDIAC FUNCTION | LVESA | LVEDA | IVC | 2D | PULSE PRESSURE | PAP | RAP CVP | SVO ₂ |
| DISTRIBUTIVE | ↑ | ↓ | ↓ / nl | ↓ / nl | | wide | nl | ↓ / nl | ↑ |
| HYPOVOLEMIC | nl / ↑ | ↓ | ↓ | ↓ | | narrow | ↓ | ↓ | ↓ |
| CARDIOGENIC | ↓ | ↑ | ↑ | ↑ | | narrow | ↑ | ↑ | ↓ |
| OBSTRUCTIVE TAMPONADE | nl / ↑ | ↓ | ↓ | ↑ | Effusion/clot RA/RV collapse | narrow | nl | ↑ | ↓ |
| OBSTRUCTIVE PE | LV ↑ RV ↓ | LV ↓ | LV ↓ | ↑ | RA/RV dilation RV failure | narrow | ↑ | ↑ | ↓ |

Different types of shock present with specific echocardiographic and hemodynamic findings. CVP, central venous pressure; IVC, inferior vena cava; LVEDA, left ventricular end-diastolic area; LVESA, left ventricular end-systolic area; nl, normal; PAP, pulmonary artery pressures; PE, pulmonary embolus; RAP, right atrial pressures; SVO₂, mixed venous oxygenation; ↑, increased; ↓, decreased.

FIGURE 33-7 ■ IVC and LVOT velocities in hypovolemia. An IVC <1.5 cm with >50% respiratory collapse suggests intravascular hypovolemia. PWD of the LVOT shows respiratory variation in velocities. IVC, inferior vena cava; LVOT, left ventricular outflow tract; PWD, pulse wave Doppler.

When assessing specific etiologies of cardiogenic shock, significant new RWMA, and new or worsening mitral regurgitation can suggest acute myocardial ischemia (Video 33-2). Valvular pathologies, dynamic LVOT obstruction, and cardiac tamponade can cause hemodynamic instability, and these problems can be diagnosed using echocardiography. Another important etiology of cardiogenic shock in the ICU is stress-induced cardiomyopathy (SCM). The incidence of this problem in ICU patients could be as high as 28%, and early diagnosis is facilitated using echocardiography.⁶⁵ Typical echocardiographic findings are apical ballooning with global LV dysfunction and compensatory hyperdynamic function of the basal segments (Video 33-3).

Right-sided heart failure, isolated or in the setting of biventricular failure, presents with slightly different echocardiographic findings. Mainly qualitative findings are depressed RV contractility, decreased EF by FAC, a TAPSE <16 mm in combination with RV dilation, RV/LV ratio of >0.8, and severe TV regurgitation (Video 33-4).⁵⁷ In this setting, low RVSP in conjunction with increased RAP, suggested by an IVC diameter >20 mm, can be due to the inability of the myocardium to create adequate pressure. Evaluation of the LV often shows signs of hypovolemia with isolated RV failure due to decreased LV preload.

The most common pathologies causing RV failure leading to acute cardiogenic shock are acute volume or pressure overload, new valvular pathologies, or acute ischemia. Chronic RV dysfunction predisposes patients to RV failure during critical illness due to noncardiogenic causes. RV dilation, TV regurgitation, ventricular septal shifts, abnormal RVSP, and IVC dilation all help to inform the clinician about the

etiology of acute RV failure. In particular, ventricular septal shifts have to be interpreted in this context, as they are commonly present in chronic valvular or pulmonary disease states, and do not necessarily indicate the presence of acute RV failure (Fig. 33-8).

Distributive Shock

Septic shock can present with a highly variable clinical picture, and dynamic changes in the appearance of shock can occur within hours with or without intervention. The clinical picture of septic shock can range from aspects of a pure distributive shock to combinations of hypovolemic, cardiogenic, and distributive shock.^{66,67} For this reason, echocardiography aids in the assessment and management of septic patients, and serial reevaluation is imperative to adapt to the dynamic evolution of the disease. Bedside echocardiography in the septic patient is focused on the systematic evaluation of volume status and fluid responsiveness, SVR, and ventricular function. Early echocardiographic signs supporting the diagnosis of septic shock are hyperdynamic LV systolic function and high CO levels in conjunction with small or normal LV EDA (Video 33-5). However, the findings will depend on intravascular volume status and RV function. It is important to differentiate between hypovolemia and low SVR in this situation, as the only distinction may be the difference in LVEDA (Video 33-1 vs. 33-5).

There are some caveats specific to the evaluation and monitoring of distributive shock. Fluid resuscitation often eliminates signs of

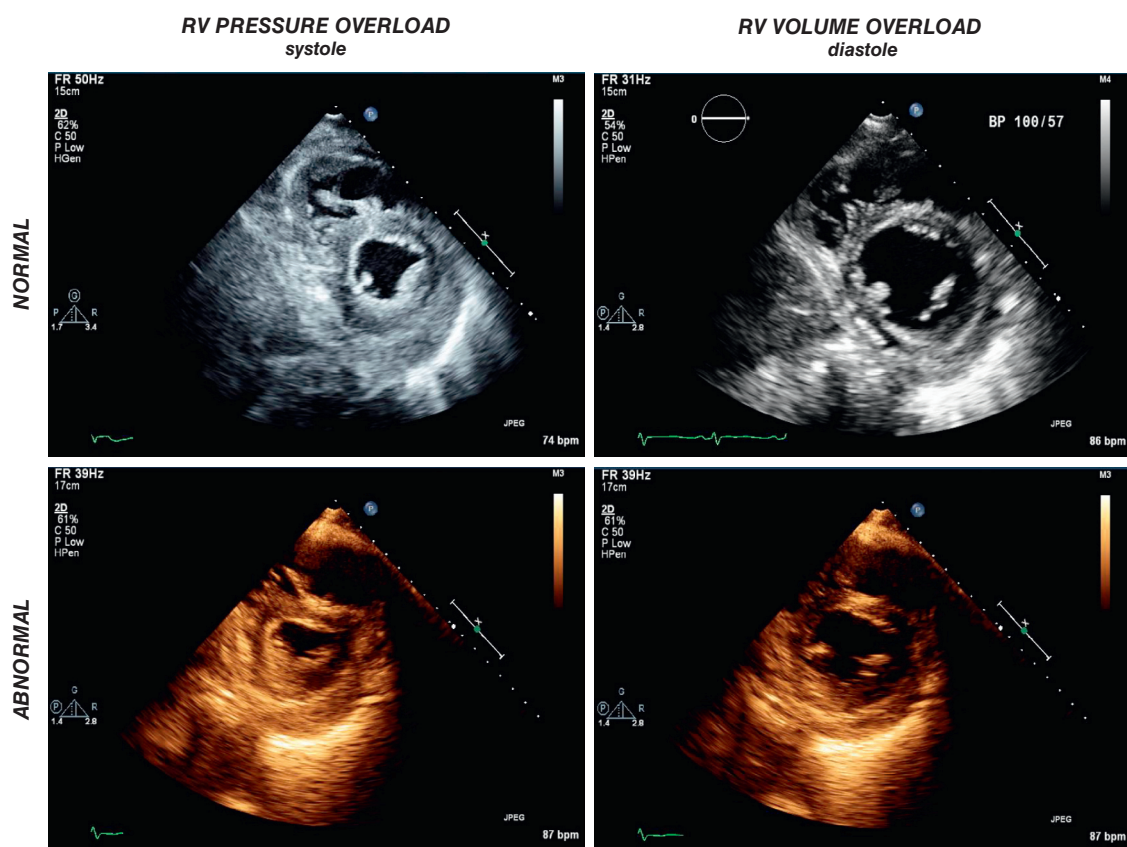

FIGURE 33-8 ■ Paradoxical interventricular septal shift. Pathologies causing RV pressure overload such as pulmonary hypertension will result in septal flattening during systole. With RV volume overload, a septal shift occurs in diastole. In acute RV failure, commonly both pathognomonic findings are seen. RV, right ventricle.

hypovolemia, and vasopressors may depress the hyperdynamic appearance of the LV. If myocardial dysfunction is present, the ventricular function may appear normal or hyperdynamic on initial or follow-up imaging as opposed to the classic hyperdynamic shock picture. Inotropic support can alter echocardiographic findings even further.⁶⁸⁻⁷⁰

Obstructive Shock

Circulatory collapse due to mechanical interference with ventricular filling or emptying is classified as an obstructive shock.⁷¹ Potential causes of obstructive shock include pericardial effusion and tamponade, tension pneumothorax, and pulmonary embolism, as well as less common entities, such as intracardiac tumors or vena cava compression. As these mechanisms are mechanical, echocardiography has the potential of visualizing the source of shock pathology directly aside from identifying the hemodynamic profile.

Pericardial effusion and cardiac tamponade are dynamic diseases closely linked to changes in intravascular volume status, intrathoracic pressures, and patient position. Although the etiology of an effusion cannot be defined by echo, certain findings such as clot formation or stranding can hint toward hemorrhagic or purulent effusions of serous fluid (Fig. 33-9). When evaluating cardiac tamponade, echocardiography can exhibit signs suggestive of hemodynamically significant pericardial effusion or clot^{72,73} (Table and Video 33-6). In postcardiac surgery patients, tamponade may not always be present with the classic circumferential effusion, and echocardiographic imaging should include an assessment for the localized clot or fluid collections in uncommon locations, such as the IVC-RA junction or posterior to the LA.

A pulmonary embolism causes the obstruction of blood flow from the right side of the heart to the left. It commonly presents with signs of right-sided pressure overload and RV failure, in conjunction with a hypovolemic and hyperdynamic LV (Table and Video 33-7).⁷⁴ The McConnell sign with akinesis of the RV free wall and normal function of the RV apex is pathognomonic but not always observed (Video 33-7).⁷⁵ Occasionally, the obstructing embolism can be seen in the very proximal pulmonary vasculature. Additionally, it is pertinent to evaluate patients for intracardiac shunts, as these present a risk for paradoxical embolism and hypoxia and have a worse short-term prognosis.^{76,77}

Tension pneumothorax can cause decreased cardiac preload, and echocardiographic findings show hypovolemia and possible mechanical cardiac compression or shift. Further imaging via chest ultrasound or radiography is necessary for the diagnosis. Other pathologies, such as extra- or intracardiac masses causing obstruction to ventricular filling, are uncommon. However, when these problems are present, echocardiography can be helpful for making the diagnosis and evaluating the hemodynamic significance.

Echocardiography during Cardiopulmonary Resuscitation

Echocardiography is part of the global use of ultrasound in cardiac arrest. It focuses on identifying the immediate causes of cardiac arrest, such as cardiac tamponade, pulmonary embolism, hypovolemia, or myocardial failure, and can guide and follow resuscitation efforts.^{78,79} Additionally, Salen et al. and Blyth et al. showed that the echocardiographic identification of cardiac activity can predict

FIGURE 33-9 ■ Hemodynamic is compromising pericardial effusion/tamponade. Respiratory variation in TV inflow of >25% is suggestive of hemodynamic-compromising pericardial effusion and tamponade. It is important to differentiate a pericardial from a pleural effusion. The arrow marks the descending thoracic aorta. A pericardial effusion does not extend superiorly (leftward) past the descending thoracic aorta, whereas a pleural effusion projects more distal to the aorta with extension past the vessel toward the left of the image. Circumferential effusion, the diastolic collapse of RA or RV, and IVC plethora are additional signs suggestive of tamponade physiology, as seen in Video 33-6.

TABLE 33-7

Echocardiographic Signs Were Seen with a Significant Pulmonary Embolism

PULMONARY EMBOLISM

- Clot in proximal pulmonary vasculature
- Depressed RV systolic function +/- hypovolemic and hyperdynamic LV
- Interventricular septum shifts consistent with RV pressure overload
- McConnell sign
- TR
- IVC plethora
- Intraatrial shunt

Dependent on the extent of RV compromise the LV will exhibit signs of hypovolemia. Classic sign of RV pressure overload shows a systolic shift of Interventricular septum. Evaluation for intraarterial communication with R to L shunting is pertinent in patients with significantly increased right-sided pressures due to PE. IVC, inferior vena cava; LV, left ventricle; RV, right ventricle; TR, tricuspid valve.

recovery of spontaneous circulation.^{80,81} The best view for immediate evaluation in cardiac arrest is the LV SAX view. This is because it can provide information about extreme changes in volume status, myocardial function, and pericardial tamponade simultaneously. Additionally, it is easy to obtain and interpret. In the acute setting, TEE can often provide better continuous imaging when chest compressions are ongoing, but it may interfere initially with intubation attempts.

■ SPECIFIC EVALUATION

Valvular Pathologies

A detailed assessment of valvular pathologies requires comprehensive echocardiographic skills and is performed by cardiologists or cardiothoracic anesthesiologists with advanced echocardiographic training. During limited ICU echocardiographic exams, the operator should seek to identify gross valvular pathologies, as their presence can alter management. Aside from the immediate adjustment in hemodynamic management, any valvular pathology found on the basic bedside exam warrants further subsequent evaluation by a comprehensive examination.

Basic components of valve assessment include gross anatomic evaluation for obvious pathologies, such as calcifications or ruptured leaflets and papillary muscles (Table 33-8). CFD is used to recognize significant transvalvular flow acceleration suggestive of stenotic lesions or patterns of valvular regurgitation of hemodynamic significance. Basic quantitative measurements of transvalvular gradients by CWD can be obtained through AV and MV for grading of stenotic lesions and calculation of valve area, but this is part of the in-depth exam.^{82,83} The five most common valvular pathologies are seen in Video 33-8 to 33-12.

Cardiomyopathies and Dynamic Outflow Obstruction

Primary disease of the heart muscle plays a significant part in the overall morbidity and mortality of cardiovascular disease. Echocardiography provides information about the magnitude of systolic and diastolic heart failure, as well as the etiology of cardiomyopathy. Echocardiography permits the assessment of immediate and long-term prognosis. As cardiomyopathies can alter the hemodynamic response to acute illnesses and their management in the ICU, it is important for the intensivist to know the echocardiographic patterns that are characteristic of these chronic disorders.⁸⁴

Cardiomyopathies (CM) are commonly differentiated into three main types: (1) dilated CM; (2) hypertrophic CM; and (3) restrictive CM.⁸⁵ Dilated CM presents with echocardiographic findings of dilated ventricles and reduced ventricular systolic function (Video 33-13). Hypertrophic CM is characterized by symmetric or asymmetric concentric hypertrophy of the myocardium (Video 33-14). It is important to recognize a dynamic obstruction of the LVOT in hypertrophic obstructive cardiomyopathy (HOCM). This is because the presence of this problem alters the usual management of cardiogenic shock management since the administration of inotropic agents can be detrimental in patients with HOCM. Dynamic outflow obstruction in these cases is caused by the systolic anterior motion of the mitral valve leaflet (SAM) (Video 33-15).⁸⁶ As in HOCM, SAM can also be present after mitral valve surgery.⁸⁷

Restrictive CM is more difficult to diagnose as it presents with diastolic dysfunction of the ventricles, and echocardiographic findings require an evaluation of diastolic function. For the intensivist, if evaluation for diastolic dysfunction is difficult, findings of atrial

TABLE 33-8 Common Valvular Pathologies and Their Echocardiographic Findings

| VALVE PATHOLOGIES | | FINDINGS |
|------------------------------|-----|---|
| Aortic stenosis (AS) | 2D | Calcification of leaflet and annulus, restrictive leaflet motion, LVH |
| | CFD | Transvalvular flow acceleration, AI |
| | CWD | Transvalvular flow acceleration, increased peak mean, and peak gradient rounded Doppler profile |
| Aortic insufficiency (AI) | 2D | Leaflet disruption, LV enlargement |
| | CFD | Regurgitant diastolic flow, turbulent flow, regurgitant jet direction |
| | CWD | Regurgitant diastolic flow, Doppler profile density, diastolic flow reversal in proximal thoracic aorta |
| Mitral stenosis (MS) | 2D | Calcification of leaflet and annulus, restrictive leaflet motion, dilated LA |
| | CFD | Transvalvular flow acceleration, PISA, MR |
| | CWD | Transvalvular flow acceleration increased peak mean and peak gradient |
| Mitral insufficiency (MR) | 2D | Leaflet pathology, chordal tethering, dilated annulus, LA enlargement, LV enlargement |
| | CFD | Regurgitant systolic flow, turbulent flow, regurgitant jet severity and direction |
| | CWD | Regurgitant diastolic flow, Doppler profile density, diastolic flow reversal in proximal thoracic aorta |
| | PWD | Pulmonary vein flows blunting/reversal |
| Tricuspid regurgitation (TR) | 2D | Dilated annulus, leaflet pathology, RA enlargement, RV enlargement |
| | CFD | Regurgitant systolic flow, turbulent flow, regurgitant jet severity and direction |
| | CWD | Regurgitant diastolic flow, Doppler profile density |
| | PWD | Hepatic vein flows blunting/reversal |

LA, left atrium; LVH, left ventricular hypertrophy; PISA, proximal isovolumetric flow acceleration.

enlargement with small ventricles and subjective restricted ventricular function are often the best supportive indicators for restrictive cardiomyopathies.⁸⁴

Infectious Pathologies and Embolic Sources

TEE is utilized in the evaluation of infectious and embolic sources in patients with unexplained sepsis or embolic strokes. In an acute setting, transthoracic findings of new regurgitant valvular lesions in the setting of bacteremia can be suggestive of infectious endocarditis. However, TEE is warranted for the optimal assessment when vegetations are anticipated (Video 33-16). As differentiation can be difficult and an evaluation for coexisting involvement of the valvular structures is pertinent for possible surgical management, comprehensive TEE is commonly performed by cardiologists.⁸⁸ When the etiology of a stroke in the absence of an infection is unclear, or in the event of planned cardioversion for prolonged supraventricular tachyarrhythmias in patients with a high risk of thrombus formation, TEE is performed to evaluate for the presence of left atrial appendage clot.^{89,90} Additionally, when evaluating for cardiac sources of thromboembolic events, the presence of intracardiac shunts as the source for paradoxical events should be ruled out. As these are not always detected by simple CFD interrogation, a bubble study during a Valsalva maneuver is performed to aid in the detection of right to left shunting.

Aortic Pathologies

Echocardiographic assessment of aortic disease in acute hemodynamic instability in critically ill patients mainly focuses on the evaluation of aortic dissection. As TTE is of limited utility for evaluation of the thoracic and abdominal aorta, TEE is the modality of choice.⁹¹ TEE has been shown to be equally accurate when compared to CT or MRI in the diagnosis and confirmation of thoracic aortic dissection.⁹² The evaluation includes the visualization of the dissection flap, identification of the true and false lumens, estimation of blood flow, and determination of active extravasation. When the aortic root is involved, assessment includes evaluation for subsequent complications, including

aortic insufficiency (AI), pericardial effusion, and acute ischemia secondary to coronary involvement.

Trauma

Echocardiography in critically ill patients after trauma can evaluate the hemodynamic status, as well as anatomic pathologies following forceful injuries.⁹³ After blunt chest trauma, echocardiography is a useful tool in the initial evaluation.⁹⁴ Catastrophic structural injuries, such as cardiac tamponade, cardiac rupture, coronary artery thrombus, disruption of valvular structures, and traumatic aortic injury, can be identified quickly.⁶¹ More commonly, patients only present with signs of cardiac contusion, and echocardiography can assist with identification of myocardial dysfunction in the acute setting. Specific TTE views are part of the standard algorithms for an emergency ultrasound, such as the FAST or FOCUS exams.^{95,96} When available and no contraindications are present, TEE is the modality of choice as it provides superior image quality and can diagnose aortic injury.⁹⁷

Interventional Use of Echocardiography

Interventional procedures involving cardiac structures are common in the ICU, and basic ultrasound and echocardiography play important roles in the conduct of these interventions. TTE or TEE performed at the bedside alleviate the need for transporting patients to the cardiac catheterization lab or procedure room for fluoroscopic guidance. This eliminates the risks that are associated with moving critically ill patients. Use of echocardiography can also decrease exposure to radiation.⁹⁸ While the basic US can assist significantly in multiple types of procedures, including venous and arterial vascular access and drainage of pleural effusions or other fluid collections, echocardiography can assist in more advanced procedures. TTE can assist with pericardiocentesis and with gross localization of a transvenous pacemaker lead.⁹⁹⁻¹⁰¹ TEE provides optimal image quality for specific cardiovascular interventions, such as an intraaortic balloon pump (IABP) placement and positioning of extracorporeal membrane oxygenation (ECMO or ventricular assist device (VAD) cannulas.^{61,102-104} TEE

best evaluates mechanical assist devices. Thromboembolic events, overt hemolysis, or fluctuation in device power or flow warrant the evaluation for thrombus formation, cannula position, and device function.^{105,106}

Hypoxemia

Echocardiography can assist in the diagnosis and management of acute respiratory failure. In pulmonary edema, differentiation between cardiogenic and noncardiogenic etiology aids in medical management. Either by invasive measurements or echocardiographic evaluation, estimation of LA and LV filling pressures is pertinent for the diagnosis of hydrostatic pulmonary edema. When a regular rhythm is present, LV filling pressures can be estimated by transmitral and pulmonary venous Doppler studies and is the most commonly used parameter for an easy, reproducible assessment in the ICU.¹⁰⁷ Common cardiac causes for pulmonary congestion are volume overload, acute mitral or aortic valve regurgitation, mitral stenosis, and severe LV systolic and diastolic dysfunction. All these problems can be assessed using 2D, CFD, and spectral Doppler echocardiographic modalities. In noncardiogenic ARDS, echocardiography can allow the clinician to assess changes in RV function with adjustments of mechanical ventilation.¹⁰⁸ Severe ARDS with increased pulmonary resistance and the use of high levels of positive end-expiratory pressure (PEEP) may lead to acute or pulmonary issues with sudden RV failure and subsequent hemodynamic and respiratory decompensation.¹⁰⁹ Similarly, acute increases in pulmonary vascular resistance due to pulmonary embolus (PE) can cause RV failure.¹¹⁰ In these cases, echocardiography is often used as a supportive tool for the diagnosis and assessment of hemodynamic significance.

Another common cause of hypoxemia in mechanically ventilated patients is the presence of intracardiac shunts. With a prevalence of >25% in the general population, intraatrial communications, such as patent foramen ovale (PFO) and atrial septum defects (ASD), are frequently clinically silent.^{111,112} In healthy patients with PFO or ASD, shunting typically is either absent or directed from left to right. During critical illness, however, increased right-sided pressure due to pulmonary hypertension, RV failure, volume overload, or TV regurgitation, is common and can lead to right to left shunting, resulting in hypoxemia due to the admixture of nonoxygenated with oxygenated blood.⁶¹ Echocardiographic evaluation focuses on detection of intracardiac shunting and directional flow of the shunt by 2D echo and CFD.

FUTURE DIRECTIONS

Many miniaturized and TTE and TEE devices have been introduced recently into the critical care environment for the use by noncardiologists for goal-directed therapy of the hemodynamically unstable patient. Handheld TTE devices demonstrate usefulness in the clinical setting when used by intensivists after undergoing brief training.¹¹³⁻¹¹⁶ Miniaturized, disposable TEE probes that provide monoplane images have been introduced for the continuous use up to 72 hours. The initial experience has demonstrated good utility in the management of hemodynamically unstable patients.^{117,118} These novel monitoring devices for continuous echocardiographic imaging have great potential for

providing many features of a regular TEE while minimizing the risks and allowing for use over a period of time.^{119,120} Advanced echocardiographic modalities, such as contrast echocardiography and endocardial border-tracking, can be valuable when available.¹²¹⁻¹²³

On the operator side, more intensivists are becoming skilled in echocardiography, and ICU fellowship programs increasingly teach focused echocardiography. With the growing importance of critical care echocardiography, critical care societies across the world propose the further integration of formal echocardiographic training into ICU fellowship training. Specific criteria are being defined for the future trainees while courses in focused ICU echocardiography are offered for the practicing intensivist.¹⁷⁻¹⁹

Despite significant advancements in the field over the past decade, a broader validation of echocardiographic use in the ICU is needed. Outcome-based studies looking at the use of focused echocardiography as a monitoring tool and integration into goal-directed therapy will be helpful in strengthening the broad use of this valuable tool.

KEY POINTS

1. TTE and TEE are valuable diagnostic and monitoring tools in the critical care setting and can have a significant impact on management and outcome of critically ill patients.
2. Training, accreditation and maintenance of expertise in focused echocardiography are essential, and further development of these areas by national societies is needed.
3. An understanding of ultrasound physiology, the echo machine, anatomy, and normal echocardiographic findings is essential for the appropriate use echocardiography in the ICU.
4. The most common use of bedside echocardiography is the evaluation of acute circulatory and respiratory failure.
5. An algorithmic approach to the hemodynamically unstable patient is warranted, and repeated echocardiographic assessment to confirm and adjust medical management needs to ensue until the patient stabilizes.
6. Interpretation of echocardiographic findings should take into account the patient's history, pathophysiology, and current medical interventions.
7. Management based on echocardiographic information needs to follow the complete clinical picture of the critically ill patient.
8. With rapid advancement in ultrasound technology, pocket-sized handheld TTE devices, and miniaturized TEE probes for continuous monitoring are being developed and will further promote the integration of focused echocardiography in the daily critical care practice.

Shock is among the most common indications for admission to the intensive care unit (ICU). As with any complex physiologic derangement, monitoring of the shock state requires constant vigilance. The ultimate goal of treating the patient with shock centers on normalizing cellular respiration and reducing the sequelae of end organ dysfunction.¹ Specific end organ tissue perfusion and oxygen utilization are difficult to measure; surrogate systemic cardiovascular metrics are used in their place. Awareness of hemodynamic trends is necessary to ensure adequate perfusion to end organs and generate a meaningful clinical response. Postoperative complications, length of hospital stay, and mortality from elective surgical procedures can be reduced by targeting therapy to meet preselected cardiovascular goals.²

Knowledge of a patient's overall volume status is profoundly important, as the goal of shock resuscitation is to normalize tissue metabolism. This usually requires optimization of end organ perfusion.³ Classically, variables such as central venous pressure, pulmonary capillary wedge pressure (PCWP), and ventricular end-diastolic volume have been used in an effort to identify the patient who will increase end organ perfusion in response to a fluid bolus. These static parameters indirectly attempt to identify a patient who is on the steep portion of the Frank-Starling end-diastolic pressure-stroke volume curve at any given point in time. These parameters are easily measured but have proven unable to identify the fluid-responsive patient. In response, modern approaches to cardiac output (CO) optimization have focused on dynamic indicators of fluid responsiveness, which identify changing conditions over time. These dynamic parameters include pulse pressure variation, stroke volume variation, change in right atrial pressure, change in aortic blood velocity, and change in vena cava diameter. All of these metrics relate to the change in stroke volume throughout the respiratory cycle, with the assumption that alterations in intrathoracic pressure, such as those that occur with ventilation, create transient physiologic swings in cardiac preload and output. They have proven to be significantly more useful in identifying the fluid-responsive patient and may lead to an improvement in clinical outcome when coupled with appropriate intervention.^{4,5}

Measurement of these dynamic parameters is complex. A variety of monitoring systems are available to follow the trend of the CO. Some devices are more effective than others, but all have advantages and limitations. They are discussed here, stratified by level of invasiveness and underlying technology. Particular attention is paid to their ability to accurately estimate CO, improvement of which is the intended outcome when treating shock. Fig. 34-1 outlines one possible approach to monitoring the patient with shock.

■ NONINVASIVE MONITORS

For the purpose of this chapter, a noninvasive cardiovascular monitoring device is defined as one that does not require arterial or central venous cannulation. While more invasive devices are certainly associated with increased potential for complications, this should not imply that noninvasive devices are not without risk of injury.^{6,7} Furthermore, by their nature, noninvasive devices indirectly measure hemodynamic parameters and thus may be prone to variability and inaccuracy.⁸

Standard Monitoring

At its most basic, noninvasive cardiovascular monitoring includes routine use of pulse oximetry, noninvasive blood pressure manometry,

and electrocardiography. Aside from physical examination, these are among the simplest and most ubiquitous tools for objective assessment of a patient's hemodynamic status. Despite their prevalence, very few prospective trials have been conducted to evaluate the independent (or grouped) impact of these monitors on clinical outcome. However, as formal hemodynamic monitoring became more accessible and widespread, anesthetic-related morbidity and mortality rate, for example, declined significantly from the 1950s to 1980s worldwide. It is impossible to know if this improvement is attributable solely to advances in monitoring. Changes in surgical populations, advances in perioperative science, secular trends, or a combination of factors may have provided additional benefit.⁹ Regardless, these basic devices are now recommended by governing societies as essential monitors during perioperative care^{10,11} and are thus unlikely to be subject to future randomized trials.

Despite lack of documented mortality benefit from routine use, basic noninvasive devices are invaluable for identifying the patient who may need advanced monitoring. Indeed, hypotension, arrhythmia and/or myocardial infarction, and hypoxemia often accompany (or precipitate) shock and can be recognized by sphygmomanometry, electrocardiography, and pulse oximetry, respectively.^{1,12,13}

Photoplethysmography

Since widespread adoption of the pulse oximeter in the 1980s, there has been a slow increase in adaptations of the underlying engineering principles of this device. Clearly, the plethysmographic signal is very similar to the arterial pressure waveform. Many investigators have attempted to extrapolate from this observation with hopes of using the waveform to estimate arterial blood pressure, systemic vascular resistance, stroke volume, and continuous CO.¹⁴⁻¹⁶ These ventures have largely been unsuccessful. Determination of volume status using respiratory variation in oximeter waveform amplitude has been especially vigorously investigated. However, these investigations have had conflicting results, and this is not considered an accurate dynamic indicator of fluid responsiveness in most settings.¹⁷

Several commercial photoplethysmographic devices are designed for continuous estimation of arterial blood pressure and are worthy of further discussion. Namely, the CNAP (CNSystems, Graz, Austria), ClearSight (formerly called NexFin; Edwards Lifesciences, Irvine, CA), and Finometer (Finapres Medical Systems, Amsterdam, Netherlands) monitoring systems take advantage of a volume-clamp technique to deliver a constant visual display of arterial pressure. The volume-clamp technique uses a very rapid feedback loop between an oximeter and inflatable finger cuffs (akin to traditional blood pressure cuffs). By rapidly increasing or decreasing the pressure in one or two cuffs to a point at which photoplethysmographic waveform oscillations are greatest, the finger's inflow artery can be held in a constant, unstretched position. At this position, the pressure in the cuffs will equal the inflow arterial pressure. Many studies have explored the accuracy of these devices compared to direct pressure transduction, but a meta-analysis concluded these devices produced imprecise and potentially inaccurate measurement of arterial pressures, larger than what was deemed acceptable.¹⁸ However, these devices are still useful to identify rapidly changing hemodynamics, such as occurs with induction of general anesthesia. More recent research has focused on the use of these systems to estimate CO, which have had some success.¹⁹ However, use of these devices for accurate continuous

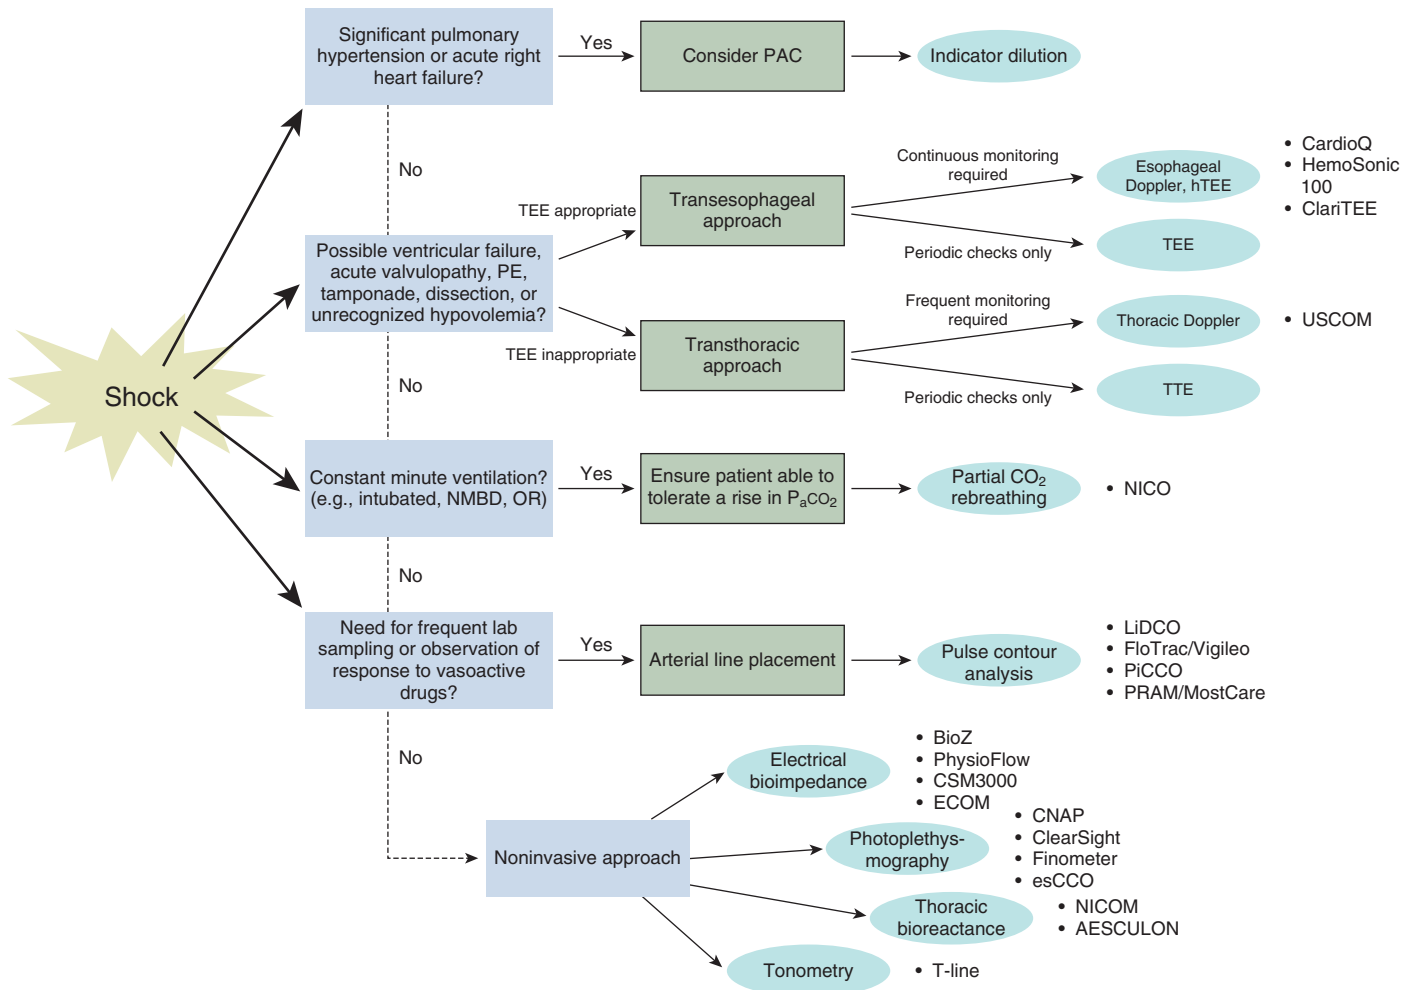

FIGURE 34-1 ■ Approach to cardiovascular monitoring strategy in the patient with shock. Detection of hemodynamic deterioration must be coupled to an appropriate intervention in order to change patient outcome. Common devices are listed, which are discussed in detail in the text. hTEE, hemodynamic transesophageal echocardiography; NMBD, neuromuscular blocking drugs; OR, operating room; PAC, pulmonary artery catheter; P_aCO_2 , partial pressure of arterial CO_2 ; PE, pulmonary embolism; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

assessment of CO (rather than at a single time point) has not been validated.

When combined with electrocardiography to estimate pulse transit time (i.e., the time from a ventricular beat until blood is delivered to the oximetry site), photoplethysmography has been successfully used to estimate short-term changes in blood pressure in patients following induction of anesthesia.^{20,21} This information can be indirectly calculated using traditional approaches or, alternatively, can be measured with the esCCO monitor (Nihon Kohden, Tokyo, Japan), which also incorporates patient-specific demographics to generate a continuous estimation of CO. Unfortunately, the esCCO device has been found to be relatively inaccurate (when not calibrated using additional data obtained invasively) compared to thermodilution approaches for estimation of CO.¹⁶

Much of the limitation in applied photoplethysmography stems from the need for significant processing to remove noise from the oximeter signal. Some of this noise reflects the influence of autonomic nervous control of vascular tone in venous or tissue oximetry; the influence of anesthesia, surgery, or critical illness on these modifiers is unpredictable and complicates interpretation. Furthermore, many of the studies evaluating the efficacy of photoplethysmography initially

show high correlation when compared with gold standard methods in healthy controls but lose fidelity when applied to critically ill patients.¹⁷ Nevertheless, photoplethysmography remains an interesting approach to hemodynamic monitoring with the potential for future clinical application.

Tonometry

Applanation tonometers electromechanically measure pressure in the radial artery, akin to estimating pressure by palpating pulse amplitude. The T-line device (Tensys Medical Inc., San Diego, CA) displays continuous radial artery pressure and also continuously calculates CO. The T-line device requires a high-quality arterial waveform signal (i.e., the tonometer needs to be optimally positioned over the radial artery), which may be challenging in a spontaneously moving patient. Of note, a 2014 meta-analysis concluded this device was too imprecise to reliably predict arterial pressure. However, this analysis focused on several commercially available noninvasive devices, including the previously discussed CNAP and ClearSight systems, and it did not stratify results by individual device. The results thus may represent unfavorable performance of other devices rather than poor T-line performance.¹⁸

When compared to transpulmonary thermodilution, the T-line system is acceptably accurate for measurement of CO in critically ill patients.²²

Electrical Bioimpedance

Originally developed in the 1960s, electrical bioimpedance systems operate on the principle that impedance varies as the total volume of fluid in the thorax changes throughout the cardiac cycle. After application of voltage-generating sensors to the thorax, bioimpedance devices measure the change between applied and detected voltage and mathematically extrapolate stroke volume from this difference. A number of bioimpedance monitors are currently marketed, including the BioZ (CardioDynamics, San Diego, CA), PhysioFlow (NeuMedX, Inc., Bristol, PA), NICOMON (Larsen and Toubro Ltd., Mumbai, India), NICCOMO (Medis, Ilmenau, Germany), and CSM3000 (Cheers Sails Medical, Shenzhen, China) devices.²³ Advantages of the bioimpedance devices include relatively low cost and ease of application. However, they are significantly confounded by the presence of extravascular lung water, improper electrode placement, presence of arrhythmia, concurrent electrical interference, and atypical systemic vascular resistance values.²⁴ In a recent meta-analysis, bioimpedance devices were found to have poor concurrence with CO measurements obtained via thermodilution techniques.²⁵ Thus, these devices are generally not recommended for long-term monitoring in a critically ill individual, but they may provide insight into CO at an isolated point in time.

A relatively newer device, the ECOM system (ConMed Corp., Utica, NY), attempts to overcome some of the limitations of traditional bioimpedance sensing by measuring intrathoracic, rather than external, impedance. This system incorporates electrodes within a specially designed endotracheal tube. Measuring impedance from within the trachea, which lies in close proximity to the aorta, may help increase accuracy by avoiding some of the noise captured with electrode placement on a patient's chest. Unfortunately, when calculating cardiac index, this approach is relatively inaccurate, though is useful for identifying fluid responsiveness. Furthermore, the ECOM system requires the presence of an arterial catheter and is therefore more appropriately considered minimally invasive.²⁶

Thoracic Bioreactance

In response to limitations of bioimpedance, thoracic bioreactance devices have been developed that process the impedance signal differently. These devices operate in similar fashion but use an expanded algorithm to detect the phase shift in transthoracic voltage (dependent on thoracic resistance and capacitance, which changes only with significant acute change in thoracic fluid volume). They detect pulsatile flow alone and are less likely to be aberrantly influenced by the presence of lung water.²⁴ Marketed bioreactance systems include NICOM (Cheetah Medical, Portland, OR) and AESCULON (Osypka Medical Services, Berlin, Germany). Despite avoiding confounding by minimizing the influence of lung water, these devices have many of the same limitations as bioimpedance devices.²³ Nevertheless, the NICOM system in particular has been found to be highly accurate in measuring CO when compared to transthoracic thermodilution measurements,²⁷ although some studies have not found it to be as accurate in critically ill patients.^{28,29}

Transthoracic Echocardiography

Complete discussion of cardiac ultrasonography is beyond the scope of this chapter. However, transthoracic echocardiography (TTE) provides invaluable insight into cardiac function and has evolved into an extraordinarily useful diagnostic tool in the ICU. In particular, TTE can assist the intensivist in recognizing ventricular failure, hypovolemia, valvular disease, pulmonary embolism, cardiac tamponade, aortic dissection, and other cardiogenic contributions to shock.^{30,31} Recent recommendations from the American Society of Echocardiography recommend a limited, focused cardiac ultrasound (FoCUS) exam,

targeting assessment of biventricular function, volume status, and gross anatomic abnormalities. This exam can be rapidly performed at the bedside and provides useful information to guide management of the unstable patient.³²

Older studies, in which exams were interpreted by cardiologists, found TTE to be highly sensitive and specific for identifying cardiogenic shock, and it often led to changes in patient management.³³ There have yet to be randomized clinical trials investigating outcomes after use of focused critical care echocardiography, partly due to the often emergent nature of the need for examination but also due to the relatively novel use of TTE as interpreted by intensivists. Nevertheless, there are data to support the use of intensivist-performed TTE, particularly in the traumatically injured or putatively hypovolemic patient.³⁴ Furthermore, initial diagnostic evaluation of the hypotensive patient is significantly faster using TTE than by placing a pulmonary artery catheter (PAC) and usually provides comparable diagnostic information.^{35,36}

Beyond evaluation of cardiac structures, thoracic ultrasonography can be used to estimate volume status by using the ventilation-induced change in inferior vena cava (Δ IVC) diameter as a dynamic parameter of fluid responsiveness. Meta-analysis suggests a large Δ IVC is effective in identifying fluid responders, further corroborating the utility of TTE as a cardiovascular monitor in the ICU.³⁷

Traditionally, the utility of echocardiography in the ICU has been limited by the need for extensive specialized training in image acquisition and interpretation. As ultrasound technology has become more affordable and common, echocardiography has increasingly permeated into medical training. Indeed, after just a few hours of formal training, one study found ICU physicians were able to estimate basic aspects of cardiac function with reasonable accuracy using TTE.³⁸

TTE does have practical limitations. While the transthoracic exam can be performed quickly, it is logistically challenging to perform repeated exams to trend cardiac function over a short time frame; continuous examination is even more cumbersome. Furthermore, the exam itself is often limited by use of positive end-expiratory pressure (PEEP), unfavorable patient habitus, suboptimal positioning, or the presence of surgical dressings.³⁸

MINIMALLY INVASIVE MONITORS

Minimally invasive monitoring devices consist of those that require low-risk cannulation of peripheral veins or arteries or device insertion into natural orifices. While increasing the risk of patient harm, they overcome some of the limitations of noninvasive devices. For practical purposes, they are among the most feasible options for advanced cardiovascular monitoring in the ICU.

Partial Carbon Dioxide Rebreathing

The Fick principle is among the oldest concepts used to estimate CO. Traditionally, the Fick method involves measuring the ratio between oxygen consumption and the arteriovenous oxygen difference. However, this same principle can be applied to other respiratory gases. Carbon dioxide (CO_2) has a high diffusion capacity, is easily quantified, and is reliably produced in end organs, making it an ideal agent for substitution into the Fick equation. Assuming the partial pressure of end-tidal CO_2 approximates mixed venous CO_2 tension, CO can be calculated by periodically permitting CO_2 rebreathing (i.e., adding dead space to the ventilatory circuit) and measuring the change in end-tidal CO_2 as compared to measurement at a nonrebreathing time. This approach has been shown to correlate with cardiac index as derived from a PAC under most conditions. The CO_2 rebreathing technique is confounded by states of low tissue production of CO_2 (e.g., hypothermia), significant shunting, and very high CO. Furthermore, constant minute ventilation is required to ensure respiratory variation does not produce large swings in arterial CO_2 tension. This method is therefore not easily applied to spontaneously breathing patients.^{39,40,41}

The NICO system (Respironics, Murrysville, PA) is a popular device that measures CO using the Fick principle. It requires knowledge of arterial oxygen tension in order to account for intracardiac or intrapulmonary shunting, hence the designation as minimally invasive. Some studies have found the NICO monitor to be accurate at estimating CO when compared to thermodilution techniques,^{41,42} but others have found poor agreement between the two approaches.^{40,43} Nevertheless, the partial CO₂ rebreathing technique remains an option for measuring CO in patients who are not breathing spontaneously, can tolerate an increase in arterial CO₂, and do not require a PAC.

It is worth noting many investigations of novel cardiovascular monitors compare CO as measured by the investigational device to the clinical gold standard of using a PAC and indicator dilution. However, the Fick approach, after measurement of systemic oxygen consumption, is an actual gold standard in itself, as it reflects end organ oxygen utilization, normalization of which is the goal of hemodynamic optimization. Fick-determined CO often, but not always, correlates well with thermodilution-determined CO.^{44,45}

Arterial Pulse Contour Analysis

Measurement of CO by analyzing the peripheral arterial waveforms began to generate widespread interest in the 1950s,⁴⁶ was further refined in the 1990s,⁴⁷ and has emerged as one of the most popular approaches to advanced cardiovascular monitoring within the past decade. By analyzing the arterial pulse waveform, stroke volume is estimated, and a continuous display of hemodynamic metrics (e.g., stroke volume, cardiac index, systemic vascular resistance, and others) is provided. Estimating CO by arterial contour analysis is complex. Briefly, stroke volume is determined by calculation of the area under the arterial pressure waveform curve, with the assumptions that blood is a non-compressible substance which must flow forward following ejection from the left ventricle, the aorta pumps blood forward as it relaxes during ventricular diastole, and there is a linear relationship between pressure and the volume of blood in the arterial bed. Ambiguity enters the equation when determining the compliance and resistance of the arterial circuit. However, total resistance is unlikely to change significantly over a relatively short time (e.g., within a single cardiac cycle), and thus the area under the arterial waveform curve is proportional to total forward flow and hence to single-beat stroke volume. Commercial devices use proprietary algorithms to estimate vascular resistance and compliance using manual calibration or known physiologic data based on patient age, height, weight, and gender.⁴⁴ There are several devices which use pulse contour analysis to measure CO. The FloTrac Vigileo (Edwards Lifesciences, Irvine, CA), LiDCO (LiDCO Ltd., London, England), PiCCO (PULSION Medical Systems AG, Munich, Germany), and the PRAM/MostCare (Vytech Health, Padova, Italy) systems are among the most popular.

The FloTrac/Vigileo has been the most frequently studied of the pulse contour analysis systems and has had several software updates since its initial introduction in an effort to refine its accuracy. It is unique in that it does not require manual calibration but is autocalibrated using biophysical data to estimate vascular compliance and resistance. This leads to the potential for erroneous measurements, particularly in critically ill patients who may not have normal arterial system dynamics. While its exact algorithm is proprietary, its method of calculating CO is based on assessing the standard deviation of arterial pressure over time, with modification by the aforementioned biophysical variables. In an oversimplified view, FloTrac/Vigileo CO = PR × sd(AP) × X, where PR represents pulse rate, sd(AP) represents pulsatility using the standard deviation of the arterial pressure wave over a 20-second interval, and X is a constant that quantifies arterial compliance and peripheral vascular resistance.⁴⁸ The most recent FloTrac/Vigileo software generation does appear to be more accurate than its predecessors. However, all versions of this device are confounded by situations with low systemic vascular resistance or high CO (e.g., patients with cirrhosis undergoing liver transplant) and can have poor agreement with traditional methods of CO estimation.⁴⁹

The LiDCO system is an alternative device that has also been well studied. This device requires calibration using lithium hemodilution every few hours. In this technique, a very small dose of lithium is injected intravenously (peripherally or centrally) to generate a lithium concentration-time curve, as measured by a lithium-sensing electrode placed within an existing arterial catheter. With this technique, LiDCO CO = (lithium dose × 60)/(area × (1 – PCV)), where PCV is packed cell volume (which needs to be subtracted in the equation as lithium is only distributed in plasma and not within red cells).⁴⁸ Several studies have shown the lithium-dilution approach to be an accurate method of assessing CO, regardless of whether the lithium is injected centrally or peripherally.^{50,51} Studies evaluating LiDCO accuracy compared to PAC-measured CO have had mixed findings. With respect to critically ill patients, the LiDCO system has been deemed accurate in stable patients who have undergone cardiac surgery or liver transplant^{52,53} but not in a group of critically ill patients with a variety of causes of shock.^{49,54}

The PiCCO system is another pulse contour analysis monitor that requires frequent calibration and has been investigated in a relatively large number of trials. PiCCO calibration requires central venous catheterization and is based on thermodilution of the injectate, as detected by a centrally placed (i.e., axillary or femoral) arterial catheter. (Thermodilution calculation of CO is discussed in more detail in the next section.) The most recent iteration of the PiCCO software also takes the shape of the arterial waveform into consideration to estimate aortic compliance and peripheral vascular resistance. Briefly, PiCCO CO = cal × HR × ∫ [P(t)/SVR + C(p) × dP/dt]dt, where cal is the patient-specific thermodilution calibration value, HR is heart rate, P(t)/SVR is the area of the waveform, C(p) is arterial compliance, and dP/dt accounts for the shape of the waveform.⁴⁸ Of note, this transpulmonary thermodilution calibration technique compares favorably with CO estimation as measured by PAC thermodilution.⁵⁵ Recently, some authors have found acceptable agreement between PiCCO and PAC-derived CO measurements during cardiac surgery.⁵⁶ However, most studies have shown unacceptable discrepancies between PAC-derived CO and PiCCO.⁴⁹

The PRAM/MostCare device is unique among pulse contour analyzers in that it does not require calibration of any sort yet provides a constant readout of CO. It operates under a proprietary pressure-recording analytic method to continually calculate beat-to-beat stroke volume. It uses data from an arterial catheter but does not use input from assumed values of aortic elastance. In a very simplified explanation, PRAM CO = HR × [A/(P/t × K)], where HR is heart rate, A is the area under the systolic portion of arterial pulse curve, P/t evaluates systolic and diastolic pressure over time, and K represents instantaneous pulsatile acceleration of the arterial cross-sectional area. It is relatively new and has been less frequently studied than the preceding approaches to pulse contour analysis. There is significant disagreement among studies regarding the accuracy of PRAM/MostCare as compared to gold-standard approaches to CO assessment, so its efficacy remains unclear.⁴⁹

Regardless of the device used, all pulse contour analysis systems require relatively stable cardiovascular conditions to estimate CO. With rapidly changing conditions, such as occur in unstable critically ill patients, many of these systems lose accuracy and precision. Furthermore, they are subject to erroneous measurement in conditions in which vascular tone may be unusually abnormal (e.g., in the presence of vasoconstricting drugs to maintain a goal mean arterial pressure), during abnormal cardiac rhythms, or in conditions in which forward flow of arterial blood may not be guaranteed (e.g., in the presence of aortic regurgitation).⁴⁴ When subject to overall pooled analysis, these devices have been found to have unacceptably large error rates. Of the individual devices, only pooled analysis of LiDCO has shown reasonable agreement with PAC-derived measurements.^{25,49} Nevertheless, these monitors may still prove beneficial in ill patients who may be harmed by insertion of a PAC, as they are capable of analyzing hemodynamic trends over time, which may be more important than the definitive identification of a precise CO. Pulse contour analysis remains

a rapidly evolving area of cardiovascular monitoring and will likely continue to see increased utility in ICUs.

Transesophageal Echocardiography

Transesophageal echocardiography (TEE) has become an invaluable tool for perioperative management of unstable surgical patients. It is an integral component of many cardiac surgical procedures, and there are well-defined guidelines for using intraoperative TEE.⁵⁷ Use of TEE for cardiovascular monitoring in the ICU is not yet routine but is increasingly common. It is often an important diagnostic modality when approaching the patient with shock who is not responding to standard therapy.⁵⁸

TEE avoids some of the limitations associated with TTE. Namely, high-quality images can often be obtained with reduced interference from patient habitus, position, or dressings. High PEEP, which can obscure the image, is also usually not a problem. Certainly there are limitations, as visualization of the left ventricle apex, portions of the left atrium, and flow across the tricuspid valve is not always easily achieved with TEE.⁵⁸ However, TEE can be rapidly performed and has been shown to frequently change patient management decisions in the ICU.^{59,60}

TEE is impractical for continuous cardiovascular monitoring. That being said, limited, goal-directed TEE exams performed over a short period of time at regular intervals can be useful to modulate therapy and assess response to interventions.^{61,62} Recently, miniaturized TEE probes have been used for hemodynamic assessment of critically ill patients with good diagnostic agreement compared to formal TEE. As of now, these miniaturized probes are only inserted periodically and removed after assessment, but they are easier to insert than full-size probes and may be safe for long-term monitoring.^{63,64} A proprietary investigational monoplane hemodynamic TEE device, the ImaCor ClariTEE (ImaCor Inc., Garden City, NY), is small in size and designed for continuous monitoring; it can remain in place for up to 72 hours. In a retrospective analysis, it was found to change therapy decisions after placement in nearly all instances of its use.⁶⁵ Further trials are necessary to determine how these less invasive TEE probes may influence patient outcome.

Doppler Ultrasound

Doppler ultrasound technology is a component of comprehensive echocardiograms based on changes in frequency that occur when ultrasound interacts with objects in motion (Doppler shift). Several devices exist that adapt the principles of Doppler echocardiography to function as cardiovascular monitors alone, rather than simply as diagnostic probes. These include the Ultrasound CO Monitor (USCOM, Sydney, Australia), CardioQ (Deltex Medical, Chichester, UK), and the HemoSonic 100 (Arrow International, Reading, PA). The USCOM is a noninvasive device that measures flow across the aortic or pulmonic valves via a handheld probe focused on the thoracic inlet or anterior chest wall. The CardioQ and HemoSonic 100 are esophageal probes that measure flow in the descending thoracic aorta. Regardless of manufacturer, all Doppler monitors measure CO over time, as calculated by the product of blood velocity multiplied by the cross-sectional area of the vessel being observed (often the descending thoracic aorta). In a pulsatile system where velocity changes throughout the cardiac cycle, velocity is summed as the velocity-time integral. Changes in the velocity-time integral reflect changes in CO, and these devices are somewhat protected from confounding caused by changes in systemic vascular resistance. The USCOM and CardioQ use proprietary algorithms to estimate vessel cross-sectional area. The HemoSonic 100 has a limited imaging tool to help measure aortic cross-sectional area and adjust the angle of the ultrasound beam relative to flow. These monitors do have several limitations. They periodically need to be refocused on the outflow tract of interest and cannot be used continuously. Improper positioning can potentially lead to incorrect aortic or pulmonary outflow tract area calculations. Additionally, abnormal relationships

between the thoracic inlet, chest wall, or esophagus and the aortic and pulmonic outflow tracts may lead to inaccurate velocity-time integral calculation.^{23,66}

These devices have not been investigated as extensively as some other modalities, and thus there are few high-quality data supporting their use. In a head-to-head comparison, there was significant disagreement between the USCOM and CardioQ systems.⁶⁷ Individually, however, they may be useful for monitoring a patient's CO trend over time. When used as part of a goal-directed strategy for optimization of perioperative fluid status, use of esophageal Doppler has been shown to be associated with fewer postoperative complications and a reduced length of hospital stay. It is unclear if these outcomes are unique to perioperative monitoring with esophageal Doppler or could be achieved using alternative dynamic assessment of volume status.⁶⁸

INVASIVE MONITORS

Invasive monitoring devices consist of those that require central venous or arterial cannulation. Invasive devices are typically reserved for patients who have specific pathologic states that mandate catheter-based assessment of cardiovascular function. Due to the complexity of this patient population and challenges associated with device insertion, these devices carry a realistic risk of infection, thrombosis, or mechanical injury.⁶⁹ If possible, the subclavian approach is preferred for central access; this carries a reduced risk of injury compared to jugular or femoral locations, though it does increase the risk of pneumothorax.⁷⁰

Central Venous Pressure Analysis

Measurement of right-sided cardiac pressure is easily accomplished after placement of a central venous line. Theoretically, assuming normal cardiopulmonary conditions, right atrial pressure should approximate left ventricular end-diastolic pressure and provide an estimate of left ventricular preload. Right atrial pressure as a static parameter has been used for more than 50 years to monitor fluid status, but it has been invalidated in many studies as an indicator of fluid responsiveness.⁷¹

Despite the limitations of central venous pressure analysis to guide resuscitation, placement of central venous lines is still necessary to deliver medication, measure venous oxygen tension, temporarily pace the heart, or treat gas embolism. Additionally, observing characteristic changes in peaks and descents in central venous pressure can be useful for diagnosing right-sided cardiac pathology such as arrhythmia, impaired diastolic relaxation, or tricuspid valvulopathy.⁷²

Pulmonary Artery Catheterization and Indicator Dilution

Introduced in 1970 by Swan and Ganz, the flow-directed PAC was among the first technologies available to allow intensivists to measure advanced hemodynamic variables.⁷³ By catheterizing the pulmonary vasculature, intensivists could now measure PCWP to estimate preload and assess CO frequently using indicator dilution. The indicator dilution approach to CO measurement involves measuring hemo- or thermodilution of an injectate as it passes from the right atrium (via a proximal catheter port) and enters the pulmonary circulation. Using this technique, $CO = [(T_b - T_i) \times V_i \times K] / (\int \Delta T_b \times dt)$, where T_b is the blood temperature, T_i is the injectate temperature, V_i is the injectate volume, K is a correction constant consisting of specific weight and specific heat of blood and injectate, and $\int \Delta T_b \times dt$ is the area under the thermodilution curve.⁷⁴ Upon introduction of this concept, it was assumed this approach could provide useful data not otherwise obtainable by less invasive examination. It was thought that would it lead to changes in management and clinical outcome. Thus, use of a PAC became a hallmark of critical care in the late 20th century.⁷⁵

The popularity of the PAC was in part due to the belief that the CO measured was accurate and that measurement of PCWP could be used

as a static indicator of volume status. However, recent work has found significant discordance between PAC- and Fick-calculated CO, especially in high-output states. Unfortunately, the lack of agreement between the methods occurs in clinically relevant conditions.⁴⁵ PAC-derived CO is prone to inaccuracy due to a variety of physiologic factors (e.g., loss of indicator solution, intracardiac shunting, tricuspid regurgitation, and respiratory variation), suggesting a possible reason for discordance between Fick- and PAC-calculated COs. Of note, transpulmonary indicator dilution, such as that employed by the LiDCO device, involves peripheral injection of an indicator solution and measuring dilution at a point distal to the heart (generally a peripheral artery). By virtue of the longer transit time, this may avoid some of the inaccuracy caused by respiratory variation.⁷⁴ Measurement of PCWP has been found to be equally fraught with challenges and can be inaccurate due to technical difficulties in wedging the catheter or zeroing the transducer. Furthermore, even when measured correctly, PCWP may not accurately estimate left ventricle end-diastolic pressure, especially in settings of reduced ventricular compliance, pulmonary hypertension, mitral valvulopathy, use of PEEP, or critical illness.⁷⁶⁻⁷⁸ Furthermore, using PCWP to optimize volume status has proven to be ineffective and has been superseded by dynamic variable assessment.⁷⁹

As evidence of the PAC's limitations accumulated, clinicians began to question the value of its routine inclusion in critical care. Certainly, inserting a PAC carries risks, not only those associated with potentially inaccurate estimations of hemodynamic variables but also the risks associated with central venous access (e.g., infection, pneumothorax, pain, and thrombosis) in addition to direct cardiac or pulmonary injury (e.g., dysrhythmia, heart block, pulmonary artery rupture, and pulmonary infarction). In 1996, the SUPPORT trial observed an increased risk of death and longer ICU stays in patients managed with PACs compared to propensity-matched controls.⁸⁰ A recent Cochrane meta-analysis including more than 5000 patients concluded PACs do not impact mortality, hospital length of stay, or cost of care.⁸¹

Much of the controversy surrounding the PAC, including its apparent lack of mortality benefit, has stemmed from studies that explicitly evaluate the impact of a PAC as a monitor alone. Many authors have expressed dissatisfaction with this approach. Their view is that the variables identified with a PAC must be coupled with goal-directed therapies, and it is these protocols that should be the focus of investigation when evaluating the impact of PACs on patient outcome. Indeed, several meta-analyses of studies that investigated perioperative therapeutic intervention protocols while monitoring hemodynamic variables using a PAC have found significant reductions in mortality, surgical complications, and postoperative organ dysfunction in patients with PACs compared to those without.⁸²⁻⁸⁴ However, these results may not be solely due to the use of a PAC for monitoring and may be achievable using other monitoring approaches. Furthermore, the mortality benefit seen in studies that use a PAC for monitoring may in fact be attributable to a hemodynamic support regimen of fluids and inotropes, as compared to studies without a PAC that have tended to use fluids alone.^{68,85}

Given the risks associated with PACs and the likelihood that goal-directed hemodynamic therapy can lead to clinical improvement using

other modes of cardiovascular monitoring, routine placement of a PAC is not recommended, even in high-risk perioperative situations. However, treatment of pulmonary hypertension and acute right heart failure necessitates monitoring pulmonary artery pressures in an effort to modulate therapy. Thus, these remain indications for a PAC.⁸⁶

CONCLUSION

Regardless of the technology or device chosen, use of cardiovascular monitoring devices should be tailored to the individual patient and circumstance. Stable, non-critically ill patients may derive the greatest benefit from relatively noninvasive approaches, with the understanding that the risk of imprecise or inaccurate data may be outweighed by the risk of harm from more aggressive approaches. Critically ill patients may require highly accurate, continuous observation of cardiovascular trends in order for the intensivist to respond rapidly and prevent further deterioration. In general, more invasive devices tend to be more precise and more accurate and thus may be indicated in this population. Ultimately, no particular approach is capable of providing direct patient benefit. Rather, it is the responsibility of the intensivist to choose a device or strategy that allows for recognition of hemodynamic derangement and encourages intervention when appropriate.

KEY POINTS

1. Monitoring devices are designed to measure global cardiovascular trends, often in an effort to accurately determine CO.
2. Dynamic, rather than static, parameters should be used to assess the cardiovascular response to an intervention, such as a fluid bolus.
3. The Fick method is the gold standard for measurement of CO, as this approach involves identification of end-organ oxygen exchange. Optimizing cellular metabolism is the goal of treatment for shock.
4. The clinical gold standard of measuring CO is that obtained by thermodilution via a PAC, as this is often more feasible than determination of systemic oxygen consumption.
5. More invasive systems, especially when they can be calibrated, offer a greater degree of accuracy and precision when calculating CO. Less invasive systems may confer a reduced risk of direct injury.
6. Critically ill patients have altered homeostasis, which may impair accuracy and precision of cardiovascular monitors.
7. In order to confer benefit, all monitoring devices require appropriate response by the intensivist when cardiovascular derangement is present.

The safe and effective management of patients with acute respiratory failure requires accurate bedside monitoring of pulmonary function. This chapter focuses on the more common noninvasive techniques for monitoring pulmonary gas exchange, respiratory system mechanics, and breathing patterns. These techniques may lead to rapid assessment of patient respiratory function and appropriate clinical action.

PULSE OXIMETRY

Pulse oximetry is a microprocessor-based instrument that incorporates both oximetry and plethysmography to provide continuous noninvasive monitoring of the oxygen saturation of arterial blood (SpO_2). Often considered the “fifth vital sign,” pulse oximetry is one of the most important technologic advances for monitoring patients during anesthesia, in the intensive care unit (ICU), on the general ward, in the emergency department, and during a wide variety of procedures.¹⁻³ The pulse oximeter probe is embedded into either a clip or an adhesive wrap and consists of two light-emitting diodes on one side and a light-detecting photodiode on the opposite side. Either a finger or an earlobe serves as the sample “cuvette.” The tissue bed is transilluminated, and the forward-scattered light is measured. Pulse oximetry targets the signal arising from the arterial bed as light absorbance fluctuates with changing blood volume. Arterial blood flow causes signal changes in light absorption (the pulsatile component called *photoplethysmography*) that can be distinguished from venous and capillary blood in the surrounding tissues (the baseline, or direct current, component; Fig. 35-1).

Oximetry uses spectrophotometry to determine SaO_2 . According to the Beer-Lambert law, the concentration of a substance can be determined by its ability to transmit light.⁴ Oxygenated hemoglobin (HbO_2) and deoxygenated or “reduced” hemoglobin (HbR) species absorb light differently, so the ratio of their absorbencies can be used to calculate saturation. In addition, there are two minor hemoglobin (Hb) species: carboxyhemoglobin (COHb) and methemoglobin (MetHb). Fractional SaO_2 is the proportion of HbO_2 relative to all four hemoglobin species:

$$\text{HbO}_2 + \text{HbR} + \text{COHb} + \text{MetHb}$$

Measuring fractional hemoglobin requires a co-oximeter that incorporates four wavelengths to distinguish each species (Fig. 35-2). In contrast, oxygen saturation as determined by pulse oximeter (SpO_2) uses two wavelengths, so that it measures functional SaO_2 :

$$\text{HbO}_2 + \text{HbR}$$

Accuracy and Precision

Because pulse oximeters themselves cannot be calibrated, their accuracy is highly variable and dependent on both the calibration curve programmed into the monitor and the quality of signal processing.^{5,6} The ratio of absorbencies is calibrated empirically against SaO_2 measured by co-oximetry in normal volunteers subjected to various levels of oxygenation. Pulse oximeters are calibrated against measured SaO_2 values down to 70% (saturation below this level are determined by extrapolation).⁵ The resulting calibration curve is stored in the monitor's microprocessor and used to calculate the SpO_2 .⁶

The accuracy of the calibration curve depends on the laboratory testing conditions (co-oximeter used, range of oxygenation studied, and characteristics of sample subjects). Most manufacturers report an accuracy of $\pm 2\%$ at an SaO_2 greater than 70% and $\pm 3\%$ when the SaO_2 is 50% to 70%.² In normal subjects tested at an SaO_2 between 99% and 83%, pulse oximetry has a bias and precision that are within 3% of co-oximetry.⁷ However, under hypoxic conditions (SaO_2 78% to 55%), when the monitor must rely on extrapolated values, bias increases (8%) and precision deteriorates (5%).⁷ Likewise, in critically ill patients, pulse oximeters historically perform well when the SaO_2 is greater than 90% (bias of 1.7% and precision of $\pm 1.2\%$), but accuracy diminishes at an SaO_2 below 90% (bias of 5.1% and precision of $\pm 2.7\%$)⁸ (Fig. 35-3). Technologic advances over the past decade have apparently improved this performance; a recent study comparing pulse oximetry to co-oximetry reported a bias of 0.19% and a precision of $\pm 2.22\%$ over an SaO_2 range of 60% to 100%.⁹

Dynamic Response

Because pulse oximeters detect very small optical signals (and must reject a variety of artifacts), data must be averaged over several seconds, thus affecting the response time.⁵ Pulse oximeters may register a near-normal SpO_2 when the actual SaO_2 is less than 70%.⁵ A prolonged lag time is more common with finger probes than with ear probes^{5,10,11} and is attributed to hypoxia-related peripheral vasoconstriction.⁵ Bradycardia is also associated with a prolonged response time.¹¹

Sources of Error

Motion artifact and low perfusion are the most common sources of SpO_2 inaccuracies, which occur because the photoplethysmographic pulse signal is very low in these settings compared with the total absorption signal.^{12,13} The combination of motion artifact and low perfusion substantially lowers SpO_2 accuracy compared with either artifact alone.¹⁴ Causes of motion artifact include shivering, twitching, agitation, intraaortic balloon pump assistance, and patient transport.^{15,16} Signs of motion artifact include a false or erratic pulse rate reading or an abnormal plethysmographic waveform. Peripheral hypoperfusion from hypothermia, low cardiac output, or vasoconstrictive drugs may increase bias, reduce precision, and prolong the time to detect a hypoxic event.¹⁶ Newer technologies have helped reduce the incidence of these problems, but they have not been eliminated as a source of error. Relocation of the probe may be required to obtain a more accurate signal.

Despite recent technologic advances, there are still a number of factors that may affect the accuracy of the pulse oximeter. Table 35-1 lists the most common factors.

Dyshemoglobins and Vascular Dyes

Significant amounts of COHb or MetHb can cause errors in SpO_2 values. COHb and HbO_2 absorb equivalent amounts of red light, so carbon monoxide poisoning results in a falsely elevated SpO_2 because the pulse oximeter reports total Hb saturation and not just HbO_2 saturation. In the setting of carbon monoxide poisoning, the amount of COHb is elevated, resulting in a falsely high SpO_2 . The patient, however, could be experiencing profound hypoxemia. In contrast, MetHb causes

FIGURE 35-1 ■ Schematic depiction of the pulse oximeter light absorption signal. (Adapted with permission from Phillips Medical Systems, Carlsbad, California.)

FIGURE 35-2 ■ Extinction coefficients of the four types of hemoglobin at the red and infrared wavelengths. Methemoglobin absorbs light at both wavelengths to an equal extent; absorption of red light by carboxyhemoglobin is similar to that of oxyhemoglobin. (From Tremper KK, Barker SJ. Pulse oximetry. *Anesthesiology* 1989;70:98-108.)

FIGURE 35-3 ■ Oxyhemoglobin dissociation curve relates oxygen saturation and partial pressure of oxygen in the blood. The curve is affected by many variables.

TABLE 35-1 Common Factors Affecting Pulse Oximetry Measurements

| FACTOR | EFFECT |
|----------------------------|---|
| Carboxyhemoglobin (COHb) | Slight reduction in accuracy of the assessment of oxygen saturation (SaO_2) by pulse oximetry (SpO_2) (i.e., overestimates the fraction of hemoglobin available for O_2 transport) |
| Methemoglobin (MetHb) | At high levels of MetHb, SpO_2 approaches 85%, independent of actual SaO_2 |
| Methylene blue | Transient, marked decrease in SpO_2 lasting up to several minutes; possible secondary effects as a result of effects on hemodynamics |
| Anemia | If SaO_2 is normal, no effect; during hypoxemia with Hb values less than 14.5 g/dL, progressive underestimation of actual SaO_2 |
| Ambient light interference | Bright light, particularly if flicker frequency is close to a harmonic of the light-emitting diode switching frequency, can falsely elevate the SpO_2 reading |
| Blood flow | Reduced amplitude of pulsations can hinder obtaining a reading or cause a falsely low reading |
| Motion | Movement, especially shivering, may depress the SpO_2 reading |
| Nail polish | Slight decrease in SpO_2 reading, with greatest effect using blue nail polish, or no change |
| Sensor contact | "Optical shunting" of light from source to detector directly or by reflection from skin results in falsely low SpO_2 reading |
| Skin pigmentation | Small errors or no significant effect reported; deep pigmentation can result in reduced signal |
| Tape | Transparent tape between sensor and skin has little effect; falsely low SpO_2 has been reported when smeared adhesive is in the optical path |
| Vasodilation | Slight decrease in SpO_2 |
| Venous pulsation | Artifactual decrease in SpO_2 |

substantial absorption of both red and infrared light, so the ratio approaches 1 (estimated SpO_2 of 85%).⁴ Significant MetHb causes falsely low SpO_2 values when the actual SaO_2 is greater than 85% and falsely high values when the SaO_2 is less than 85%.⁴ Administration of methylene blue or indocyanine green dyes for diagnostic tests causes a false, transient (1- to 2-minute) drop in SpO_2 to as low as 65%.^{17,18}

Nail Polish and Skin Pigmentation

Both dark skin pigmentation and dark nail polish interfere with absorption of the wavelengths used by pulse oximetry. Pulse oximeters thus have greater bias and less precision in black patients.⁸ Whereas an SpO_2 of 92% is sufficient to predict adequate oxygenation in white patients, a saturation of 95% is required in black patients.⁸ Dark nail polish can falsely lower SpO_2 , whereas red polish tends not to affect pulse oximetry accuracy.¹⁹ However, with newer technology, the negative effects of nail polish have been lessened. A recent study showed that there was an effect of dark nail polish on pulse oximetry readings, but it was not clinically relevant.²⁰ When nail polish cannot be removed, mounting the oximeter probe sideways on the finger yields an accurate reading.²¹

Ambient Light, Anemia, and Hyperbilirubinemia

Although pulse oximeters compensate for the presence of ambient light, the sensor should be shielded from intense light sources with an opaque material. Falsely low SpO_2 readings occur when even minor gaps exist between the probe and skin, allowing light reflected off the skin's surface to "shunt" directly to the photodiode.²² Xenon surgical lamps and fluorescent lighting can cause a falsely low SpO_2 .²³ Under

conditions of anemia (Hb 8 g/dL) and severe hypoxia (SaO₂ 54%), SpO₂ bias is markedly increased (−14%).²⁴ Hyperbilirubinemia does not affect SpO₂ directly.²⁵ However, carbon monoxide is a byproduct of heme metabolism, and icteric patients tend to have higher levels of COHb,²⁵ so SpO₂ may be falsely elevated.

Reflectance Pulse Oximetry

Reflectance pulse oximetry was designed to counter signal-detection problems associated with finger probes during hypoperfusion. The reflectance sensor is designed for placement on the forehead just above the orbital area, where superficial blood flow is abundant and less susceptible to vasoconstriction.²⁶ Whereas traditional probes work by transilluminating a tissue bed and measuring the forward-scattered light on the opposite side of the finger or earlobe, reflectance probes are constructed with the light-emitting diodes and the photodetector located on the same side. The photodetector measures the back-scattered light from the skin.²⁶ In addition, more liberal placement sites for reflectance pulse oximetry have allowed fetal monitoring during labor.²⁷ Intraesophageal SpO₂ monitoring is currently under investigation.²⁸ Anasarca, excessive head movement, and difficulty in securing the probe site are some of the problems encountered with reflectance pulse oximetry.²⁹ Light “shunting” from poor skin contact and direct sensor placement over a superficial artery are associated with artifacts.³⁰ Reflectance pulse oximetry is also limited by poor signal-to-noise ratio and variability among sites in the arrangement of blood vessels and tissue blood volume.³⁰ However, recent studies have shown reflectance pulse oximetry to be as effective as finger sensors in many situations.^{31–34}

Technologic Advances

Recent advances in signal analysis and processing have markedly improved SpO₂ accuracy during low perfusion states and reduced the problem of motion artifact.^{16,35} According to recent independent testing, these advances occur with pulse oximeters made by several manufacturers.³⁶ Durban and Rostow reported that new pulse oximeter technology can accurately detect SaO₂ in 92% of the cases in which traditional SpO₂ monitoring failed owing to low perfusion and motion artifact³⁷ (Box 35-1).

CAPNOMETRY

Capnometry consists of the measurement and numeric display of expired carbon dioxide (CO₂) at the patient's airway opening.³⁸ When a waveform plotting CO₂ against time or volume is also displayed, it is referred to as *capnography*, and the waveform is referred to as a *capnogram*.³⁸ Capnometry is most commonly used on patients receiving mechanical ventilation and works by passing infrared light through a sample chamber to a detector on the opposite side. CO₂ absorbs infrared light at a peak wavelength of approximately 4.27 μm.^{38,39} More infrared light passing through the sample chamber (i.e., less CO₂) causes a larger signal in the detector relative to the infrared light passing through a reference cell. The sample chamber is either connected directly to the Y-adapter of the ventilator circuit (mainstream) or by a sampling line at the Y-adapter that continuously aspirates gas into a sampling chamber located inside the monitor (sidestream).

Clinical Applications

Capnometric determination of the partial pressure of CO₂ in end-tidal exhaled gas (PETCO₂) is used as a surrogate for the partial pressure of CO₂ in arterial blood (PaCO₂) during mechanical ventilation^{40,41} (Fig. 35-4). Although widely available today, the utilization of PETCO₂ to represent PaCO₂ in ICUs remains unclear. While perhaps not an exact match for PaCO₂, PETCO₂ does provide a valuable trending tool. Also, with newer technologies, the accuracy of PETCO₂ measurements is improving. In a recent study, McSwain et al. showed strong correla-

BOX 35-1

American Association for Respiratory Care (AARC) Clinical Practice Guideline: Pulse Oximetry

INDICATIONS

- The need to monitor the adequacy of arterial oxyhemoglobin saturation.
- The need to quantitate the response of arterial oxyhemoglobin saturation to therapeutic intervention or to a diagnostic procedure (e.g., bronchoscopy).
- The need to comply with mandated regulations or recommendations by authoritative groups.

CONTRAINDICATIONS

- The presence of an ongoing need for measurement of pH, PaCO₂, total hemoglobin, and abnormal hemoglobins may be a relative contraindication to pulse oximetry.

PRECAUTIONS

- Pulse oximetry is considered a safe procedure, but because of device limitations, false-negative results for hypoxemia and/or false-positive results for normoxemia or hyperoxemia may lead to inappropriate treatment of the patient.
- Factors that may affect pulse oximeter readings include motion artifact, abnormal hemoglobins and methemoglobin, intravascular dyes, exposure of measuring probe to ambient light during measurement, low perfusion state, skin pigmentation, and nail polish or nail coverings with finger probe.

ASSESSMENT OF NEED

- When direct measurement of SaO₂ is not available or accessible in a timely fashion, an SpO₂ measurement may temporarily suffice if the limitations of the data are appreciated.
- SpO₂ is appropriate for continuous and prolonged monitoring (e.g., during sleep, exercise, bronchoscopy).
- SpO₂ may be adequate when assessment of acid-base status and/or PaO₂ is not required.

ASSESSMENT OF OUTCOME

- The following should be utilized to evaluate the benefit of pulse oximetry:
 - SpO₂ results should reflect the patient's clinical condition (i.e., validate the basis for ordering the test).
 - Documentation of results, therapeutic intervention (or lack of), and/or clinical decisions based on the SpO₂ measurement should be noted in the medical record.

MONITORING

- The monitoring schedule of patient and equipment during continuous oximetry should be correlated with bedside assessment and vital sign determinations.

From AARC clinical practice guideline: pulse oximetry. *Respir Care* 1992;37:891-897.

tions between PETCO₂ and PaCO₂ across a wide range of dead-space conditions.⁴² Capnometry is used for a variety of purposes, such as in the diagnosis of a pulmonary embolism, determination of lung recruitment response to positive end-expiratory pressure (PEEP), detection of intrinsic PEEP, evaluation of weaning, as an indirect marker of elevated dead-space ventilation, assessment of cardiopulmonary resuscitation, indirect determination of cardiac output through partial CO₂ rebreathing, verification of endotracheal cannulation, detection of airway accidents, and even determination of feeding tube placement.^{43–55} Guidelines for the use of capnometry/capnography are outlined by the American Association for Respiratory Care (Box 35-2).

Paco₂-PETCO₂ Gradient

Normal subjects have a PaCO₂-PETCO₂ gradient of 4 to 5 mm Hg.^{40,43,47,56–60} In critically ill patients, the PaCO₂-PETCO₂ gradient can be markedly elevated, with a tendency toward wider gradients in obstructive lung diseases (7–16 mm Hg) than in acute lung injury or cardiogenic pulmonary edema (4–12 mm Hg).^{46,47,61–63} A strong correlation between ΔPETCO₂ and ΔPaCO₂ ($r = 0.82$), along with minor bias and reasonable precision between PETCO₂ and PaCO₂, suggests that arterial blood gas monitoring may not be needed to assess ventilation unless the ΔPETCO₂ exceeds 5 mm Hg.⁴⁸ Nevertheless, several studies have found

FIGURE 35-4 ■ Single-breath carbon dioxide waveform depicts carbon dioxide elimination as a function of the volume of gas exhaled. Phase 1 represents gas exhaled from the upper airways. Phase 2 is the transitional phase from upper to lower airway ventilation and tends to reflect changes in perfusion. Phase 3 is the area of alveolar gas exchange and represents changes in gas distribution. PETCO₂, partial pressure of end-tidal carbon dioxide.

that the Δ PETCO₂ often falsely predicts the degree and direction of Δ PaCO₂.^{58-60,63} Therefore, despite PETCO₂ monitoring, routine arterial blood gas analysis is still required in critically ill patients.

Several factors determine the PaCO₂-PETCO₂ gradient. Whereas PaCO₂ reflects the mean partial pressure of CO₂ in alveolar gas (PaCO₂), PETCO₂ approximates the peak PaCO₂.⁶⁴ During expiration, lung regions with high ventilation-to-perfusion ratios dilute the mixed CO₂ concentration so that PETCO₂ is usually lower than PaCO₂.⁶⁵ However, when CO₂ production is elevated (or expiration is prolonged), PETCO₂ more closely resembles mixed venous PCO₂, as a higher amount of CO₂ diffuses into a progressively smaller lung volume.⁶⁴ Thus, the PaCO₂-PETCO₂ gradient can be affected by changes in respiratory rate and tidal volume (VT) because of alterations in expiratory time and by CO₂ production and mixed venous CO₂ content.⁶⁴ In fact, it is not uncommon for PETCO₂ to exceed PaCO₂.⁶⁵ Inotropic or vasoactive drugs may affect the PaCO₂-PETCO₂ gradient in an unpredictable manner, either by increasing cardiac output and pulmonary perfusion (thereby reducing alveolar dead space) or by reducing pulmonary vascular resistance and magnifying intrapulmonary shunt by countering hypoxic pulmonary vasoconstriction.⁵⁸

Mechanical factors can cause either inconsistencies or inaccuracies in PETCO₂. The sample tubing length and aspirating flow rates used in sidestream capnometers affect the time required to measure changes in tidal CO₂ concentration.⁶⁶ At respiratory frequencies above 30 breaths/minute, capnometers tend to underreport the true PETCO₂.⁶⁷ This may occur because of gas mixing between adjacent breaths during transport down the sampling line and in the analysis chamber.⁶⁷ This problem can be avoided with mainstream analyzers, which provide near-instantaneous CO₂ measurement (less than 250 msec).⁶⁸

PaCO₂-PETCO₂ Gradient, Positive End-Expiratory Pressure, and Lung Recruitment

PEEP recruits collapsed alveoli, improves ventilation-perfusion matching, and reduces alveolar dead space, although excessive levels cause overdistention and increased alveolar dead space.⁶⁹ Because the PaCO₂-PETCO₂ gradient correlates strongly with the physiologic dead space-to-tidal volume ratio (VD/VT), this gradient may be useful in titrating PEEP in patients with acute lung injury (ALI) or acute respiratory distress syndrome (ARDS).^{49,50} An animal model of ARDS found that stepwise application of PEEP progressively reduced the PaCO₂-PETCO₂ gradient and coincided with maximal or near-maximal improvements in oxygenation.⁶¹ However, PEEP applied beyond the lowest PaCO₂-

BOX 35-2 American Association for Respiratory Care (Aarc) Clinical Practice Guideline: Capnography/Capnometry During Mechanical Ventilation

INDICATIONS

- Capnography should not be mandated for all patients receiving mechanical ventilatory support, but it may be indicated for:
 - Evaluation of the exhaled CO₂, especially end-tidal CO₂ (PETCO₂).
 - Monitoring severity of pulmonary disease and evaluating response to therapy, especially therapy intended to improve the ratio of dead space to tidal volume (VD/VT) and the matching of ventilation to perfusion (V/Q) and, possibly, to increase coronary blood flow.
 - Use as an adjunct to determine that tracheal rather than esophageal intubation has taken place.
 - Continued monitoring of the integrity of the ventilatory circuit, including the artificial airway.
 - Evaluation of the efficiency of mechanical ventilatory support by determination of the difference between PaCO₂ and PETCO₂.
 - Monitoring adequacy of pulmonary, systemic, and coronary blood flow.
 - Estimation of effective (nonshunted) pulmonary capillary blood flow by a partial rebreathing method.
 - Use as an adjunctive tool to screen for pulmonary embolism.
 - Monitoring inspired CO₂ when CO₂ gas is being therapeutically administered.
 - Graphic evaluation of the ventilator-patient interface.
 - Measurement of the volume of CO₂ elimination to assess metabolic rate and/or alveolar ventilation.

CONTRAINDICATIONS

- There are no absolute contraindications to capnography in mechanically ventilated patients, provided the data obtained are evaluated with consideration given to the patient's clinical condition.

PRECAUTIONS AND POSSIBLE COMPLICATIONS

- With mainstream analyzers, the use of too large a sampling window may introduce an excessive amount of dead space into the ventilator circuit.
- Care must be taken to minimize the amount of additional weight placed on the artificial airway by the addition of the sampling window or, in the case of a sidestream analyzer, the sampling line.

ASSESSMENT OF NEED

- Capnography is considered a standard of care during anesthesia. The American Society of Anesthesiologists has suggested that capnography be available for patients with acute ventilatory failure on mechanical ventilatory support. The American College of Emergency Physicians recommends capnography as an adjunctive method to ensure proper endotracheal tube position.
- Assessment of the need to use capnography with a specific patient should be guided by the clinical situation. The patient's primary cause of respiratory failure and the acuteness of his or her condition should be considered.

ASSESSMENT OF OUTCOME

- Results should reflect the patient's condition and should validate the basis for ordering the monitoring.
- Documentation of results (along with all ventilatory and hemodynamic variables available), therapeutic interventions, and/or clinical decisions made based on the capnogram should be included in the patient's chart.

MONITORING

- During capnography, the following should be considered and monitored:
 - Ventilatory variables: tidal volume, respiratory rate, positive end-expiratory pressure, inspiratory-to-expiratory time ratio (I:E), peak airway pressure, and concentrations of respiratory gas mixture.
 - Hemodynamic variables: systemic and pulmonary blood pressures, cardiac output, shunt, and ventilation-perfusion imbalances.

From AARC clinical practice guideline: capnography/capnometry during mechanical ventilation. *Respir Care* 2003;48:534-539.

PETCO₂ gradient caused a secondary rise in the gradient, along with decreased cardiac output. Although a subsequent trial was unable to reproduce these findings in humans, another study found that the PaCO₂-PETCO₂ gradient narrowed (from 14 to 8 mm Hg) and oxygenation improved when PEEP was set at the lower inflection point of the

pressure-volume curve.^{45,62} When PEEP was set 5 cm H₂O above the lower inflection point, the PaCO₂-PETCO₂ gradient rose to 11 mm Hg, and cardiac output trended downward. In patients without a lower inflection point, the PaCO₂-PETCO₂ gradient did not change in response to PEEP. Thus, in a subset of ARDS patients, the PaCO₂-PETCO₂ gradient may be an effective way to titrate PEEP.

PETCO₂ Monitoring During Cardiopulmonary Resuscitation

Monitoring end-tidal CO₂ concentration is a reliable method for evaluating the effectiveness of cardiopulmonary resuscitation.⁷⁰ In animal models, PETCO₂ is strongly correlated with coronary perfusion pressure and successful resuscitation,⁷¹ whereas in humans, changes in PETCO₂ are directly proportional to changes in cardiac output.⁷² PETCO₂ during precordial compressions can distinguish successful from unsuccessful resuscitation, with values greater than 10 mm Hg⁷³ or greater than 16 mm Hg⁷⁴ associated with successful resuscitation.

Measurement of Dead-Space Ventilation

Ventilation-perfusion abnormalities are the primary physiologic disturbance in nearly all pulmonary diseases and the principal mechanism for elevated PaCO₂.⁷⁵ Dead-space ventilation (VD), the portion of VT that does not encounter perfused alveoli, directly impacts CO₂ excretion and is used as an indirect measure of ventilation-perfusion abnormalities. Physiologic VD represents the summation of anatomic-conducting airway and nonperfused alveolar components.

Physiologic VD/VT has historically been measured during a 3- to 5-minute exhaled gas collection into a 30- to 60-L Douglas bag. An arterial blood gas reading is obtained during the midpoint of the collection. VD/VT is calculated using the Enghoff modification of the Bohr equation, whereby the difference between PaCO₂ (a surrogate for the mean PaCO₂) and mean expired CO₂ tension (PECO₂) is divided by PaCO₂:

$$\frac{VD}{VT} = \frac{PaCO_2 - PECO_2}{PaCO_2}$$

The dead-space volume per breath or per minute can be determined by multiplying VD/VT by the simultaneously measured average VT or minute ventilation (\dot{V}_E)⁷⁶:

$$VD = \frac{(PaCO_2 - PECO_2)}{PaCO_2} \times VT \text{ or } VD = \frac{(PaCO_2 - PECO_2)}{PaCO_2} \times \dot{V}_E$$

By subtracting the physiologic VD per minute from the \dot{V}_E , the alveolar minute ventilation is obtained ($\dot{V}_A = \dot{V}_E - \dot{V}_D$). It can also be calculated as the volume of CO₂ produced per minute (\dot{V}_{CO_2}) divided by the PaCO₂:⁷⁶

$$\dot{V}_A = \frac{\dot{V}_{CO_2}}{PaCO_2} \times 0.863$$

Although expired gas collection with a Douglas bag is the classic method for measuring VD/VT, the gas collection system requires additional valving and connectors, making the procedure time-consuming and awkward. Metabolic monitors produce equally accurate, reliable results and are less cumbersome.^{77,78} The Douglas bag method and metabolic monitors, however, do share a limitation when used on a mechanically ventilated patient. During mechanical ventilation, gas is compressed in the circuit, which dilutes the fractional expired CO₂ concentration.⁷⁹ A correction factor can be used to offset the mathematical effects of gas compression. Volumetric capnography is an alternative method of measuring PECO₂ and VD/VT and has the advantage of being measured at the patient, thus eliminating the effects of compression volume contamination and the need to apply a correction factor.⁸⁰ In patients with ARDS, it has been shown that measurements of VD/VT using volumetric capnography are as accurate as those obtained through the use of a metabolic monitor.⁸¹ In addition, newer monitors incorporating capnography and pneumotachygraphy provide accurate single-breath determinations of VD/VT.⁸²

A significant source of measurement error for VD/VT is the contamination of expired gas with circuit compression volume.⁸³ During positive-pressure ventilation, part of the VT is compressed in the circuit, and during expiration, this gas mixes with CO₂-laden gas from the lungs. The dilution of the expired CO₂ results in a falsely elevated VD/VT that is directly proportional to the peak inspiratory pressure and circuit compliance. Clinically, correcting VD/VT for compression volume is done by multiplying the measured PECO₂ by the ratio of the ventilator-set VT to the VT delivered to the patient.⁸⁴ This requires determination of the ventilator circuit compliance.

Clinically, VD/VT may assist in the management of pulmonary disease in terms of both ventilator adjustments and diagnostic testing. Suter and colleagues found that VD/VT decreased as lung units were recruited but increased with lung overdistention during PEEP titration in ARDS.⁶⁹ A more recent study involving the use of dead-space calculations in ARDS showed that increased dead space is associated with a higher mortality in the early and intermediate phases of ARDS.⁸⁵ Fletcher and Jonson used VD/VT to optimize VT and inspiratory time settings during general anesthesia.⁸⁶ Measuring VD/VT may assist in identifying patients who can be removed from mechanical ventilation. Hubble and coworkers found that values less than 0.50 predicted successful extubation, and values greater than 0.65 identified patients at risk for post extubation respiratory failure.⁸²

One of the main clinical uses of VD/VT is to aid in the diagnosis of acute pulmonary embolism. VD/VT is comparable to radioisotopic lung scanning in detecting acute pulmonary embolism, with a value less than 0.40 suggesting that a significant embolus is improbable.⁸⁷ Single-breath estimates of alveolar VD are also capable of identifying patients with pulmonary embolus.⁸⁸ Increased physiologic VD/VT (greater than 0.60) was found to be significantly associated with mortality in patients with ARDS and in neonates with congenital diaphragmatic hernia.^{89,90} The findings that VD/VT is elevated early in the course of ARDS and is associated with increased mortality may be particularly useful. The efficacy of new therapies for ARDS may be judged, in part, by their ability to reduce VD/VT.

Transcutaneous Monitoring

Transcutaneous blood gas monitoring involves the use of a skin surface sensor to provide continuous noninvasive estimates of arterial PO₂ and PCO₂ (TcO₂ and TcCO₂, respectively). The sensor warms the skin to promote arterialization, as well as to increase the permeability of the skin to O₂ and CO₂ (Fig. 35-5). Elements of the sensor include a heating element, O₂ electrode, and CO₂ electrode. The electrodes measure the gas tensions in an electrolyte gel located between the sensor and the skin. Similar to end-tidal CO₂ (ETCO₂) monitoring and pulse oximetry, transcutaneous monitoring has the potential advantages over

FIGURE 35-5 ■ A combined SpO₂/TcPCO₂ sensor at the earlobe. (From Eberhard P. The design, use, and results of transcutaneous carbon dioxide analysis: current and future directions. *Anesth Analg* 2007;105: S48-S52.)

direct arterial blood gas sampling of reducing the amount of blood drawn, time spent for analysis, and associated costs. $TcCO_2$ tends to be more reliable, most likely because of the greater diffusion capacity of CO_2 through the skin and the skin's own O_2 consumption.⁹¹ $TcCO_2$ has historically been used more frequently in neonatal and pediatric populations, but recent technologic advances have led to increased utilization in adults, despite the effects of a thicker epidermis. It has been shown to be particularly accurate in neonates because of their thin, poorly keratinized skin, which has fewer barriers to diffusion of capillary gases.⁹²

The gradient between $TcCO_2$ and $PaCO_2$ is influenced by skin perfusion and skin temperature. Thus, factors affecting cutaneous vasoconstriction (e.g., vasopressors, cardiac output, cutaneous vascular resistance) could potentially influence $TcCO_2$ measurements. Technical factors that can affect the accuracy of $TcCO_2$ measurements are similar to those of $ETCO_2$ monitoring and center around the inevitable gradient with $PaCO_2$.

The accuracy of transcutaneous arterial blood gas measurement in adults remains a point of debate. A number of studies have shown that $TcCO_2$ monitoring is accurate in adult patients with respiratory disorders.⁹³⁻⁹⁶ Some studies even suggest that $TcCO_2$ monitoring may be more accurate than $ETCO_2$ monitoring owing in part to the elimination of dead space.⁹⁷⁻⁹⁹ Conversely, some reports suggest that $TcPO_2$ is not accurate enough to be used clinically in the adult population or even in preterm infants.^{100,101}

The use of transcutaneous arterial blood gas measurement is increasing, but it should not take the place of invasive arterial blood gas measurement; it may have a place in trending oxygenation and CO_2 levels. However, care must be taken to ensure that variables that could affect the readings have been eliminated and that the unit is calibrated per the manufacturer's specifications, especially when erroneous readings are suspected.

ASSESSMENT OF PULMONARY MECHANICS

Assessment of basic pulmonary mechanics is crucial to monitoring pulmonary function during mechanical ventilation. It requires the measurement of VT , peak inspiratory flow rate, and four pressures: peak airway pressure, end-inspiratory plateau pressure, end-expiratory pressure in the circuit, and if intrinsic PEEP is suspected, end-expiratory pressure measured during an end-expiratory pause maneuver. From these variables, the compliance and resistance of the respiratory system are determined.

Compliance

Under conditions of passive mechanical ventilation, peak airway pressure denotes the total force necessary to overcome the resistive and elastic recoil properties of the respiratory system (i.e., both lungs and chest wall). Compliance is expressed as the ratio of volume added to pressure applied. Dynamic compliance is the ratio of volume added to the peak airway pressure (Paw) and includes the resistive forces in the tracheobronchial tree. A more useful measurement is that of static compliance. Static compliance requires the use of an end-inspiratory hold.¹⁰² During an end-inspiratory pause, peak airway pressure dissipates down to a stable plateau pressure. At the end of the inspiratory hold maneuver, "static" conditions usually exist (resistive forces have been eliminated), and the corresponding "plateau pressure" represents the elastic recoil pressure.

Dividing the VT by the plateau pressure ($Pplat$) minus the PEEP yields the static compliance of the respiratory system ($Crs\text{-stat}$).¹⁰³ Even at moderate levels of \dot{V}_E (greater than 10 L/min), dynamic gas trapping can occur (intrinsic PEEP) and, if suspected, $Crs\text{-stat}$ must be calculated using total PEEP ($PEEP_{tot}$) measured during an end-expiratory pause, rather than the PEEP applied at the airways¹⁰⁴:

$$Crs\text{-stat} = \frac{VT}{Pplat - PEEP_{tot}}$$

During patient-triggered ventilation, the assessment of pulmonary mechanics becomes more difficult because of the patient's spontaneous contributions, which may falsely raise or lower the plateau pressure. Obtaining an accurate measurement requires that the clinician perform the inspiratory hold when spontaneous efforts are absent and the pause will most likely be of shorter duration.

Resistance

Respiratory system resistance (Rrs) is the ratio of driving pressure to flow.¹⁰⁵ It is calculated as the difference between Paw and $Pplat$ divided by the preocclusion peak inspiratory flow rate (\dot{V}_I) and expressed as cm H_2O/L per second¹⁰⁶:

$$Rrs = \frac{Paw - Pplat}{\dot{V}_I}$$

Resistance is flow dependent because the driving pressure necessary to overcome resistance increases disproportionately to changes in \dot{V}_I (due to increased turbulence).¹⁰⁷ Therefore, respiratory system resistance can be accurately determined only with a constant inspiratory flow (square wave) pattern.¹⁰⁶

Compliance and Resistance in Normal and Pathologic Conditions

In mechanically ventilated normal patients, compliance is 57 to 85 mL/cm H_2O , and resistance is 1 to 8 cm H_2O/L per second.¹⁰⁸⁻¹¹⁰ Abnormalities in compliance and resistance in patients with acute respiratory failure are dependent on both the cause and severity of the disease. Patients with ARDS or cardiogenic pulmonary edema tend to have a low compliance (35 or 44 mL/cm H_2O , respectively) and an elevated resistance (12 or 15 cm H_2O/L per second, respectively).¹¹¹ In contrast, patients with chronic airway obstruction tend to have both a higher compliance (66 mL/cm H_2O) and a higher resistance (26 cm H_2O/L per second).¹¹¹

Dynamic Gas Trapping and Intrinsic Positive End-Expiratory Pressure

At end expiration, if the respiratory system remains above its relaxed position, gas gets trapped and the elastic recoil pressure in the lungs remains above baseline and is considered positive. This phenomenon is referred to as *intrinsic PEEP* ($PEEP_i$).¹¹² $PEEP_i$ can be measured by an end-expiratory circuit occlusion maneuver, whereby after a normal expiratory time elapses, both the inspiratory and expiratory ventilator valves close for 3 to 5 seconds, allowing alveolar pressure to equilibrate with the airway pressure (see Fig. 35-3).^{113,114} This pressure represents the average $PEEP_i$ throughout the lungs.^{113,115} However, it is important to keep in mind that different degrees of $PEEP_i$ may coexist in the lungs because of regional variations in time constants due to the underlying pathology.^{114,115} $PEEP_i$ is more common in mechanically ventilated patients with chronic obstructive lung diseases (in which dynamic hyperinflation slows elastic recoil) and patients who require high respiratory rates (which allow inadequate time for complete exhalation).

Pressure-Volume Curves

The static pressure-volume relationship can be used to analyze the elastic properties of the respiratory system and help guide mechanical ventilation.¹¹⁶ Pressure-volume (P-V) curves usually have a sigmoidal shape (Fig. 35-6). When inflation begins below functional residual capacity (FRC), there is relatively little volume change as transpulmonary pressure increases. This is referred to as the *starting compliance* and corresponds to the first 250 mL of volume change.¹¹⁷ It reflects either the relatively high pressure required to overcome small airway closure in the dependent lung zones or the relatively small area of aerated lung tissue as inflation commences.^{117,118} Typically this low-compliance segment in the P-V curve is followed by an abrupt slope change with a concave appearance that is termed the *lower inflection*

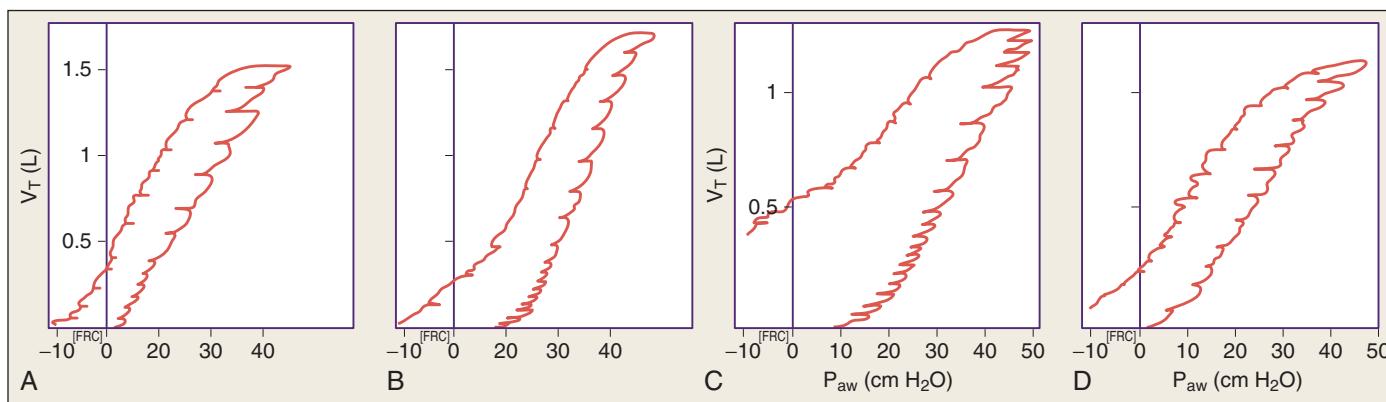

FIGURE 35-6 ■ Pressure-volume curves of the respiratory system of patients in various phases of acute respiratory distress syndrome. **A**, Decreased compliance and little hysteresis (early fibroproliferative phase). **B**, Almost normal compliance with large hysteresis (early exudative phase). **C**, Decreased compliance with large hysteresis (later exudative phase). **D**, Low compliance and little hysteresis (late fibroproliferative phase). (From Bigatello LM, Davignon KR, Stelfox HT. Respiratory mechanics and ventilator waveforms in the patient with acute lung injury. *Respir Care* 2005;50:235-245.)

point,¹⁰⁰ or Pflex.¹⁰¹ A common interpretation of the lower inflection point is that it signifies an abrupt reopening of collapsed peripheral airways and alveoli.^{116,118-120} Above the lower inflection point, the P-V curve becomes linear and is referred to as the *inflation compliance*.¹²¹ As the total lung capacity is approached, compliance decreases and the P-V curve becomes convex (bow-shaped). This is referred to as *end compliance*¹²¹ and is thought to signify the loss of distensibility at maximal inflation.¹¹⁸ This change point is termed the *upper inflection point*.¹²¹ As the lung is deflated, the linear portion of the curve is referred to as the *deflation compliance*, or *true physiologic compliance*, as it represents the elastic properties of the lung after full recruitment.¹²² As lung deflation proceeds below FRC, an inflection point often occurs on the deflation limb that represents small-airway closure.¹²² This airway closure tends to occur at a lower pressure than the lower inflection point on the inflation limb because the minimal force necessary to maintain patent airways is less than the pressure needed to recruit collapsed ones.¹²³

Constructing a Pressure-Volume Curve

There are three general approaches for creating the P-V curve: the supersyringe method, constant flow method, and multiple occlusion method.^{121,124,125} The supersyringe method involves the use of a large syringe that can accommodate up to 2 L of volume. At exhalation, insufflated volumes and the resulting pressures are recorded (after a 2- to 3-second pause at each point to eliminate the resistive forces) in a stepwise fashion (usually 100-mL increments).¹²⁵ Usually, when the airway pressure reaches the 40-cm H₂O range, inflation is stopped and deflation is performed the same way. Volume steps are plotted against the corresponding static pressure points on graph paper to obtain the curve. Respiratory system compliance is the slope of the inflation and deflation curves between the volumes of 0.5 and 1 L.¹¹⁹ The disadvantages of the supersyringe method are that it requires additional equipment, the patient has to be disconnected from the ventilator, and patient paralysis is required.

The constant flow method is available on some ventilators and involves the use of very low inspiratory and expiratory flows. The ventilator will then display the P-V plot. Higher flows, though, will allow the viscoelastic properties of the lung to shift the curve to the right. Disadvantages of this method include the fact that some ventilators cannot control expiratory flow (the deflation limb would be inaccurate) and, in most instances, the patient will require additional sedation so as not to contribute any spontaneous respiratory efforts.

The multiple occlusion method is also done with the ventilator. It involves periodically interrupting tidal breathing at different lung

volumes to obtain each P-V point. The ventilator, as was the case with the constant flow method, then displays the P-V plot. The advantages of this method are that both the inflation and deflation limbs are obtained, and the patient does not have to be disconnected from the ventilator. Sedation, paralysis, or both are still required with this method to prevent spontaneous respiratory efforts.

Determination of Lower and Upper Inflection Points

In clinical practice, the lower inflection point of the inflation limb is usually determined by the graphic technique.⁹⁷ First, a tangent is drawn extending the slope of the starting compliance. Another tangent is drawn extending the slope of the inflation compliance down toward the horizontal axis. Where the two tangents intersect, a third tangent is drawn down to the horizontal axis, and this point is considered the lower inflection point. The same technique can be used to determine the upper inflection point on the inflation limb, as well as the deflation limb's lower inflection point. Typically, PEEP is set 2 cm H₂O above the lower inflection point to ensure optimal lung recruitment, and VT is set below the upper inflection point to prevent lung injury from excessive stretch.^{116,126} P-V curves obtained through the use of a ventilator require visual interpretation of the inflection points. The problem with visual interpretation is that the inflection points are not always completely evident. This can lead to differing interpretations among clinicians.

Hysteresis

Hysteresis refers to the difference in compliance during inflation versus deflation. Compliance tends to be higher during deflation than inflation because higher pressures may be required during inspiration to recruit collapsed alveoli. This "extra" pressure is not required during deflation to prevent derecruitment. Ultimately then, the deflation limb may be more important for setting PEEP, since the deflation limb inflection point represents the point at which the alveoli will collapse.¹²⁷

ASSESSMENT OF BREATHING PATTERN AND CENTRAL DRIVE

Rate and Tidal Volume

Basic assessment of the respiratory pattern includes the measurement of respiratory rate and VT. A normal respiratory rate is 12 to 24 breaths/min, and mechanical ventilation is generally indicated when the rate exceeds 35 breaths/min.¹²⁸ A VT of 5 mL/kg is considered

sufficient to maintain unassisted breathing.¹²⁹ Tachypnea is often the earliest sign of impending respiratory failure, even when arterial blood gases remain within normal limits.¹³⁰ This may reflect the fact that muscle fatigue (which results from a mechanical workload that exceeds the power capacity of the ventilatory muscles) occurs before overt ventilatory pump failure.¹³¹ If untreated, a rapid, shallow breathing pattern can develop that will be progressively ineffective in maintaining acceptable arterial blood gases.¹³²

Of particular interest is the utility of breathing pattern in assessing the feasibility of weaning from mechanical ventilation. Typically, patients who fail to wean are more tachypneic (respiratory rate greater than 32 breaths/min) and have an abnormally low V_T (less than 200 mL).¹³³ The respiratory rate- V_T ratio, also known as the rapid shallow breathing index (RSBI), is a method that helps in evaluating readiness to wean. The RSBI is thought to be an accurate predictor of breathing effort.^{134,135} An RSBI threshold of less than 105 has both a high positive predictive value (0.78) and high negative predictive value (0.95) for the ability to maintain unassisted breathing.¹³⁶ Although the utility of RSBI has support from various studies,^{137,138} the original negative predictive value, at a cutoff greater than 105, may be too low according to some authors.^{138,139} While not an absolute predictor in and of itself, RSBI can be a valuable tool in helping to predict readiness to wean.

Central Ventilatory Drive

In some situations, clinicians may want to assess the central ventilatory drive. A heightened drive will increase the patient's work of breathing during mechanical ventilation.¹⁴⁰ Measuring the respiratory rate will give the clinician an indication of the central ventilatory drive but not the depth of the drive. Depth of the drive can be measured by a brief (100 msec) inspiratory occlusion after the onset of an effort, called $P_{0.1}$. Briefly occluding the airway at the onset of inspiratory

effort results in isometric contraction of the inspiratory muscles, so $P_{0.1}$ is independent of respiratory system mechanics.¹⁴¹ Measuring airway pressure at 100 msec indirectly reflects efferent motor neuron output. An increasing stimulus to the inspiratory muscles causes a more forceful contraction, with a proportional increase in pressure development. The selection of 100 msec is based on the fact that conscious or nonconscious perception of (and response to) sudden load changes requires approximately 250 msec.¹⁴² It is convenient that during mechanical ventilation, the lag associated with the trigger phase provides sufficient time to measure $P_{0.1}$.¹⁴³ Some ventilators¹⁴⁴ and pulmonary mechanics monitors¹⁴⁵ now measure $P_{0.1}$. Experimentally, $P_{0.1}$ has been used for closed-loop control of pressure support levels during weaning from mechanical ventilation.¹⁴⁶

At rest, $P_{0.1}$ is normally 0.8 cm H₂O, whereas in patients with respiratory failure, it can range from 2 to 6 cm H₂O, depending on the level of ventilatory support.^{143,145,147-150} $P_{0.1}$ correlates highly with a patient's work of breathing, and changes in $P_{0.1}$ (which occur with ventilator adjustments) show a high degree of sensitivity and specificity for corresponding changes in patient work.^{151,152} $P_{0.1}$ has been used to predict weaning and extubation success in patients recovering from acute respiratory failure. Levels exceeding 6 cm H₂O may predict weaning failure in chronic obstructive lung disease, whereas a $P_{0.1}$ greater than 4 cm H₂O may presage failure in ARDS.^{153,154}

During brief trials of unassisted breathing, a $P_{0.1}$ greater than 7 cm H₂O tends to describe patients requiring total ventilatory support and has been reported as a cutoff level in patients who ultimately fail a trial of extubation.¹⁵⁵ $P_{0.1}$ values between 4 and 7 cm H₂O may indicate patients who can be managed with partial ventilatory support, whereas a value less than 4 cm H₂O may indicate patients no longer in need of mechanical assistance.¹⁵⁴

A limitation of $P_{0.1}$ is that it dissociates from ventilatory drive when muscle weakness is present or hyperinflation alters the force-length relationship of the inspiratory muscles.

KEY POINTS

Pulse Oximetry

1. Because pulse oximeters cannot be calibrated, their accuracy is highly variable and dependent on both the calibration curve programmed into the monitor and the quality of signal processing.
2. Carboxyhemoglobin and oxyhemoglobin absorb equivalent amounts of red light, so carbon monoxide poisoning can result in falsely elevated oxygen saturation as measured by a pulse oximeter (SpO_2).
3. Motion artifact and low perfusion are the most common sources of SpO_2 inaccuracies.
4. Falsely low SpO_2 readings occur when even minor gaps exist between the probe and skin.
5. Pulse oximeters have greater bias and less precision in patients with dark skin pigmentation.

Capnometry

1. In normal subjects, the gradient between partial pressure of carbon dioxide in arterial blood and partial pressure of carbon dioxide in end-tidal exhaled gas (P_{aCO_2} - P_{ETCO_2} gradient) is 4 to 5 mm Hg, whereas in critically ill patients, the P_{aCO_2} - P_{ETCO_2} gradient can be markedly elevated and inconsistent, particularly in those with obstructive lung diseases (7 to 16 mm Hg).
2. The P_{aCO_2} - P_{ETCO_2} gradient is affected by changes in respiratory rate, tidal volume, carbon dioxide (CO_2) production, and mixed venous CO_2 content.

3. At respiratory frequencies above 30 breaths/min, capnometers tend to underreport the true P_{ETCO_2} .
4. In some patients with acute respiratory distress syndrome, the P_{aCO_2} - P_{ETCO_2} gradient may be an effective way to titrate positive end-expiratory pressure (PEEP).
5. During precordial compressions, P_{ETCO_2} can distinguish between successful and unsuccessful resuscitation, with values greater than 10 mm Hg associated with successful resuscitation.

Assessment of Pulmonary Mechanics

1. Distinguishing resistive from elastic recoil-related pressures in the lungs requires the introduction of an end-inspiratory circuit occlusion after tidal volume delivery.
2. In clinical practice, the pause time used for an end-inspiratory circuit occlusion is set at 0.5 to 1 second to limit any potential artifact from spontaneous breathing efforts that may falsely raise or lower the end-inspiratory plateau pressure.
3. The driving pressure necessary to overcome resistance increases disproportionately to changes in gas flow, so resistance can be determined accurately only with a constant inspiratory flow (square wave) pattern.
4. Intrinsic PEEP is measured by occluding both limbs of the ventilator circuit for 3 to 5 seconds at end-expiration, thus allowing alveolar pressure to equilibrate with airway pressure. This pressure represents the average intrinsic PEEP throughout the lungs.

Continued

KEY POINTS—cont'd

5. When using the pressure-volume curve of the respiratory system for lung-protective ventilation in patients with acute respiratory distress syndrome, PEEP is set 2 cm H₂O above the lower inflection point to ensure optimal lung recruitment, and tidal volume is set below the upper inflection point to prevent lung injury from excessive stretch.

Assessment of Breathing Pattern, Strength, and Central Drive

1. A threshold value of less than 105 for the respiratory rate/tidal volume ratio has both a high positive predictive value (0.78) and

high negative predictive value (0.95) for the ability to maintain unassisted breathing.

2. During brief trials of unassisted breathing, an inspiratory occlusion pressure 100 msec after the onset of effort ($P_{0.1}$) greater than 7 cm H₂O tends to signify patients requiring total ventilatory support and has been reported as a cutoff level in patients who ultimately fail a trial of extubation.

ANNOTATED REFERENCES

Alberti A, Gallo F, Fongaro A, et al. $P_{0.1}$ is a useful parameter in setting the level of pressure support ventilation. *Intensive Care Med* 1995;21:547-553.

This paper describes the potential use of $P_{0.1}$, an indirect measurement of central respiratory drive and inspiratory effort, as a simple method for both titrating the level of mechanical ventilatory support and assessing weaning tolerance.

Falk JL, Rackow EC, Weil MH. End-tidal carbon dioxide concentration during cardiopulmonary resuscitation. *N Engl J Med* 1988;318:607-611.

This landmark paper introduced one of the most important clinical applications of capnography: the monitoring of spontaneous circulation and the effectiveness of precordial compressions in the setting of cardiac arrest. A sudden rise in end-tidal CO₂ concentration from approximately 1% to 3% (7 to 20 mm Hg) coincides with the return of spontaneous circulation.

Nuckton TJ, Alonso JA, Kallet RH, et al. Pulmonary dead-space fraction as a risk factor for death in acute respiratory distress syndrome. *N Engl J Med* 2002;346:1281-1286.

This study provides the first evidence that a pulmonary-specific variable can independently predict the risk of death in patients with ARDS. Dead-space fraction may prove to be a useful measurement by which to judge the efficacy of future therapies for ARDS.

Pepe PE, Marini JJ. Occult positive end-expiratory pressure in mechanically ventilated patients with airflow obstruction. *Am Rev Respir Dis* 1982;126:166-170.

This case series report introduced one of the most crucial concepts and monitoring imperatives of invasive mechanical ventilation. This description of the mechanics and clinical implications of dynamic hyperinflation remains one of the most lucid in the critical care and pulmonary literature.

Tremper KK, Barker SJ. Pulse oximetry. *Anesthesiology* 1989;70:98-108.

This paper remains one of the best written on the subject of pulse oximetry. It provides clinicians with an elegant discussion of the history, physics, engineering, and clinical aspects of this technology.

While arterial blood gas (ABG) data provide critical information to practitioners of critical care medicine, ABG measurement is the most frequently ordered test in intensive care units (ICUs), is overutilized, and is associated with burden to our patients (discomfort, blood loss) and healthcare system.¹⁻⁵ Therefore, appropriate understanding and use of this clinical test are important for optimal care of our patients. Although no randomized trials have been published to date, clinical studies looking at the utility of ABG testing in relation to clinical outcomes have reported mixed results and strongly suggest that ABG information be used within the clinical context in the ICU.⁶⁻⁸ The development of polarographic electrodes in the 1950s for oxygen (O₂) by Clark and for carbon dioxide (CO₂) by Severinghaus and Bradley, as well as Stow and coworkers, permitted measurement of the partial pressures of oxygen (Pao₂) and carbon dioxide (Paco₂) in arterial blood.⁹⁻¹¹ Cremer and colleagues developed the pH electrode in the early 20th century. ABGs remain the definitive method to diagnose, categorize, and quantitate respiratory, as well as metabolic, failure.¹²

WHY AM I OBTAINING AN ARTERIAL BLOOD GAS?

This should be the primary question to ask ourselves as part of our practice before reflexively ordering the next ABG upon encountering an unstable patient. As noted above, ABG measurement is the most frequently performed test in ICUs, and studies suggest that the presence of an arterial line is the most powerful predictor for obtaining an arterial blood sample for ABG, regardless of the Pao₂, Paco₂, Acute Physiology and Chronic Health Evaluation (APACHE) II score, or presence of a ventilator.^{1,13} In addition, there are no published guidelines and only a limited number of trials providing guidance to clinicians regarding the indications for sampling ABGs.¹⁴ Roberts et al., as well as Murphy, demonstrated that protocolized care was able to reduce the number of unnecessary ABGs with no negative effects on patient outcomes.^{1,4}

The indications for ABG analysis have to be guided within the clinical context, and recent technologies such as pulse oximetry and transcutaneous CO₂ detection will decrease the frequency of use of ABGs.^{15,16} Yet, we still need to give clinicians a “rule of thumb” regarding when to sample ABGs. As such, patients need ABG

- following endotracheal intubation and/or mechanical (invasive or noninvasive) ventilation,
- during the clinical course of acute respiratory distress syndrome (ARDS),
- when hypoxemic and/or hypercapnic respiratory failure is present,
- when acute circulatory failure is present, and
- during the management of complex acid-base disorders.

ARTERIAL BLOOD GAS SAMPLING

ABG samples are obtained either from an indwelling arterial catheter or from direct arterial puncture, and the blood is drawn into a syringe containing heparin. It used to be customary to flush a syringe with heparin and then to use that syringe to sample ABGs; however, research in adult, as well as pediatric, patients has shown that excess heparin significantly decreases the Paco₂, Pao₂, bicarbonate (HCO₃⁻), and base excess, while leaving the pH unchanged. Thus, excess liquid heparin falsely exaggerates the degree of metabolic acidosis with respiratory compensation.^{17,18}

While the most common site for arterial puncture is the radial artery, femoral and brachial arteries are also commonly used to sample arterial blood. Risks associated with arterial punctures are hematoma formation, ischemia to the upper or lower extremity, arterial injury, pseudoaneurysms, and arteriovenous fistulas.^{14,19-22} Once obtained, the arterial blood sample has to be processed immediately and correctly using the best laboratory practices to ensure quality. In addition to differences among laboratories, calibration discrepancies and contamination of electrodes with protein or other fluids may alter results.^{23,24}

Using the polarographic electrodes, Pao₂, Paco₂, and pH are directly measured; oxygen saturation (SaO₂) is calculated from standard O₂ dissociation curves or directly measured with a co-oximeter.^{9-12,25}

A co-oximeter is a blood gas analyzer that measures not just the partial pressure of gases but also the concentration of oxygen associated with different types of hemoglobin (Hb) based on their absorption spectra (Beer-Lambert law). The use of co-oximetry is usually indicated when

- a toxin is suspected,
- hypoxia fails to improve with the administration of oxygen,
- there is a discrepancy between the Pao₂ on a blood gas determination and the oxygen saturation determined by pulse oximetry (SpO₂), or
- a clinician suspects the presence of a dyshemoglobin, such as methemoglobin (MetHb) or carboxyhemoglobin (COHb).²⁶

Pulse oximetry, unfortunately, does not differentiate among the different types of Hbs. For example, in the case of MetHb, the Spo₂ may read 86%, but desaturation can be demonstrated with co-oximetry, recording 68% oxyhemoglobin and 32% MetHb.^{26,27}

The HCO₃⁻ concentration is calculated using the Henderson-Hasselbalch equation:

$$\text{pH} = \text{pK}_A + \log\left(\frac{[\text{HCO}_3^-]}{[\text{CO}_2]}\right),$$

where pK_A is the negative log of the dissociation constant of carbonic acid (HCO₃⁻).

The *base excess* is the quantity of strong acid required to titrate blood to pH 7.40 with a Paco₂ of 40 mm Hg at 37°C. In reality, acid is not titrated but calculated using a variety of nomogram.²⁸⁻³² Such calculations focus only on the metabolic sources for pH and [H⁺] changes. Bicarbonate is a similarly calculated value assuming Paco₂ at 40 mm Hg.

The following are some of the details one must take into consideration to avoid erroneous readings and interpretations:

1-Steady State

The sample of blood for ABG testing has to be collected when a patient reaches a steady state during the clinical course, especially to allow the arterial and alveolar gases to equilibrate. This may take up to 20 or 30 minutes in patients with chronic obstructive pulmonary disease (COPD).³³

2-Anticoagulants

As mentioned in the [Arterial Blood Gas Sampling](#) section, excessive heparin may affect Paco₂, Pao₂, HCO₃⁻, and base excess, while not interfering with the pH. Only 0.05 mL is required to anticoagulate 1 mL of blood, and knowing that the “dead space” volume of a standard 5-mL syringe is approximately 0.02 mL, it is reasonable to assume that

just having heparin in the dead space would be sufficient to provide anticoagulation of up to 2 mL of blood. New prefilled syringes (sodium or lithium heparin) overcome this problem.¹⁷

3-Processing Delay

While the blood sample resides in the syringe before analysis, the blood cells consume O₂ and produce CO₂. Red blood cell glycolysis could generate more lactic acid through the aerobic glycolysis and lower the pH.^{34,35} If the sample remains unanalyzed at room temperature for more than 15 minutes, there would be a significant increase in PaCO₂ and decrease in pH. When the sample is stored on ice, it can be processed up to 2 hours after collection without affecting the blood gas values, even on Mount Everest.³⁶⁻³⁹

4-Venous Sampling

If no arterial blood sample can be obtained, venous blood gas analyses would be of limited value; however, such a venous sample could give an estimate of the PaCO₂ and lactate concentration.^{40,41} This will be discussed later in the chapter.

There could be times when the intended arterial puncture results in inadvertent venous sampling. One can recognize venous sampling when

- the practitioner fails to observe a flash of blood during syringe filling,
- the blood gas results are not consistent with the clinical condition,
- there is an unexpectedly low Pao₂ and high Paco₂, or
- the Spo₂ by pulse oximetry is higher than the Sao₂ in the measured ABG sample.

5-Collection Equipment and Technique

If the dead space in the syringe were high, this would lower the PaCO₂. Additionally, a needle smaller than 25 gauge may cause hemolysis.

If there is an arterial line, one has to pay attention to the dead space of the system (priming volume from the sample port to the catheter tip) to prevent sample dilution. The adequate amount of blood to discard before obtaining the sample of blood for testing would be 2 times the dead space volume.³

6-Hyperventilation

Hyperventilation resulting from anxiety and/or pain may acutely alter the ABG results, producing deviations from baseline values.

7-Leukocytosis

Leukocytosis decreases the Pao₂ and pH and elevates the Paco₂ when analyzing a stored sample. This Pao₂ decrease is particularly noticeable in the presence of higher Pao₂ levels, is attributable to cellular oxygen consumption, and may be attenuated when samples are stored at colder temperatures.

8-Hypothermia

Blood gas values are temperature-dependent, and as the temperature decreases, the solubility of CO₂ increases and the partial pressure falls. Thus, if blood samples are warmed to 37°C before analysis (as is common in most laboratories), Pao₂ and Paco₂ will be overestimated and pH will be underestimated in hypothermic patients. The following correction formulas can be used:

- Subtract 5 mm Hg Pao₂ per 1°C that the patient's temperature is less than 37°C.
- Subtract 2 mm Hg Paco₂ per 1°C that the patient's temperature is less than 37°C.

- Add 0.012 pH units per 1°C that the patient's temperature is less than 37°C.

While there is extensive literature on the so-called pH-stat and alpha-stat assessments of ABGs, in summary, the *pH-stat* acid-base approach aims at maintaining the patient's pH in a constant range by managing pH at the patient's temperature. As in the formulas above, pH-stat is temperature-corrected. On the other hand, *alpha-stat* focuses on the ionization state of histidine, which is maintained by managing the standardized pH (measured at 37°C). Alpha (normally about 0.55) is the ratio of protonated imidazole to total imidazole on the histidine moieties in proteins. Alpha-stat is not temperature corrected—as the patient's temperature falls, the partial pressure of CO₂ decreases and solubility increases; thus, a hypothermic patient with a pH of 7.40 and a Paco₂ of 40 (measured at 37°C) will actually have a lower Paco₂ because of its lower partial pressure, and this will manifest as a *relative respiratory alkalosis*. In contrast, pH-stat, with its goal of maintaining a Paco₂ of 40 and pH of 7.40 at the patient's actual temperature, results in a higher Paco₂ (and *respiratory acidosis*).⁴³⁻⁴⁵

HYPOXEMIA, HYPOXIA, AND ARTERIAL BLOOD GAS ANALYSIS

We need to clarify the definitions of hypoxemia and hypoxia and the utility of different measures prior to analyzing the results of ABGs. The Pao₂ is primarily used to assess oxygenation, and it is reliable within a dynamic range between 30 to 200 mm Hg. However, Sao₂ is reliable within a much narrower range: between 30 and 60 mm Hg.⁴⁸ Measuring oxygen saturation by noninvasive pulse oximetry (Spo₂) or by ABG analysis (Sao₂) provides a better indication of arterial O₂ content than Pao₂, since only about 2% of blood O₂ is carried in the dissolved form and the greatest amount (98%) is carried by Hb. While using the Spo₂, one has to be cognizant of its shortcomings, including interference by indicator dyes used during certain procedures.^{49,50}

Hypoxemia is defined as a Pao₂ less than 80 mm Hg at 1 atm in adults breathing room air; *hypoxia* denotes tissue or cell level decreases in O₂. Thus, hypoxia (tissue or end-organ) in patients with hypoxemia depends on the severity of the hypoxemia and the ability of the cardiovascular system to compensate. Hypoxia is unlikely in mild hypoxemia (Pao₂ = 60-79 mm Hg). Moderate hypoxemia (Pao₂ = 45-59 mm Hg) may be associated with hypoxia in patients with anemia or cardiovascular dysfunction. Hypoxia is almost always associated with severe hypoxemia (Pao₂ < 45 mm Hg). While the Pao₂ might be low at 45 mm Hg, the mitochondrial O₂ partial pressure necessary to complete oxidative phosphorylation is around 0.5 to 3 mm Hg, several orders of magnitude lower, which may be the reason why some patients with cyanotic diseases and elite Mount Everest climbers without supplemental oxygen can have an average Pao₂ of 26 mm Hg, yet survive without significant end-organ injury.⁵¹⁻⁵⁸

Acute respiratory insufficiency occurs when the lungs no longer meet the metabolic demands of the body. It is divided into two types:

- Type I, hypoxemic respiratory insufficiency: Pao₂ ≤ 60 mm Hg when breathing room air at 1 atm pressure.
- Type II, hypercapnic respiratory insufficiency: Paco₂ ≥ 50 mm Hg.
- The tripartite information that can be gathered from ABG analyses includes (a) oxygen saturation and content, (b) CO₂ as a marker of ventilation, and (c) acid-base status. Here, we will discuss all three components.

Alveolar Ventilation

The Paco₂ reflects the CO₂ content of the sample. The CO₂ content is basically the balance between the quantity of CO₂ produced and the quantity excreted through alveolar ventilation (VA). It can be expressed by the equation:

$$\text{Paco}_2 \sim \text{CO}_2 / \text{VA}$$

VA is the portion of total ventilation that participates in gas exchange with pulmonary blood. If the metabolic rate remains unchanged, it is reasonable to assume that CO_2 production is in steady state. CO_2 homeostasis can then be simplified to:

$$\text{PaCO}_2 \sim 1/\text{VA}$$

Therefore, when steady state is reached (as discussed earlier in the chapter), PaCO_2 becomes a useful tool for assessing VA. If the PaCO_2 is >45 mm Hg, this is referred to as *alveolar hypoventilation*, and if the PaCO_2 is <35 mm Hg, it is called *alveolar hyperventilation*.

Oxygenation

Tissue oxygenation is dependent on the delivery of oxygenated blood (both dissolved as well as bound to Hb). The PaO_2 is the dissolved fraction that makes a very small contribution to O_2 delivery ($<2\%$), yet this fraction could be critical and useful in the setting of severe anemia.^{59,60} PaO_2 is dependent on the concentration of inspired oxygen (FiO_2), ventilation and perfusion (V/Q) matching, and venous oxygen saturation (SvO_2). The PaO_2 value has to be assessed within a clinical context, along with the FiO_2 and age of the patient.

Relationship Between PaO_2 and FiO_2

PaO_2 alone provides limited information about oxygenation and alveolocapillary gas exchange unless FiO_2 is also considered in the interpretation. In addition to FiO_2 , the other major determinant of PaO_2 is the degree of intrapulmonary shunting (Fig. 36-1). While PaO_2 and FiO_2 alone do not quantitate the intrapulmonary shunt (which is useful for the diagnosis and management of lung diseases and in guiding the approach to oxygen therapy and respiratory support), they provide an overall indication about the diagnosis, after which various formulas can be used for calculating the intrapulmonary shunt (Q_s/Q_t).

The classic “shunt equation” requires mixed venous blood sampling through a pulmonary artery catheter and the alveolar-arterial oxygen gradient equation (Box 36-1):

$$Q_s/Q_t = (C_c\text{O}_2 - C_a\text{O}_2)/(C_c\text{O}_2 - C_v\text{O}_2), \text{ where}$$

Q_s is blood flow through the shunt,

Q_t is total cardiac output,

$C_c\text{O}_2$ is pulmonary end-capillary O_2 content,

FIGURE 36-1 ■ The effect of increasing FiO_2 on PaO_2 according to shunt fraction.

$C_a\text{O}_2$ is arterial O_2 content, and

$C_v\text{O}_2$ is mixed venous O_2 content.

Clinically, the so-called P/F ratio ($\text{PaO}_2/\text{FiO}_2$) is most commonly used to approximately quantify the degree of V/Q mismatching. Since the normal PaO_2 in an adult breathing room air at an FiO_2 of 21% is 80 to 100 mm Hg, the normal value for $\text{PaO}_2/\text{FiO}_2$ ranges between 400 and 500 mm Hg. A $\text{PaO}_2/\text{FiO}_2$ ratio <200 most often indicates a shunt of $>20\%$. This ratio has also been incorporated since 1994 into the ARDS definition.⁶¹⁻⁶³ A notable limitation of the $\text{PaO}_2/\text{FiO}_2$ ratio is that it does not take into account changes in PaCO_2 at low FiO_2 .

Age

PaO_2 decreases with age (Box 36-1). For example, at an FiO_2 of 21% and 1 atm pressure, the PaO_2 is 85 to 90 mm Hg at 60 years of age, and this value decreases to 80 to 85 mm Hg at 80 years of age.

Acid-Base Balance

The normal diet generates volatile acid (CO_2) primarily from carbohydrate metabolism and nonvolatile acid (hydrogen ion [H^+]) from protein metabolism. The function of the homeostatic system is to maintain pH within a narrow range, and pH homeostasis is accomplished through the interaction of the lungs, kidneys, and blood buffers. VA allows for excretion of CO_2 , and the kidneys reclaim filtered HCO_3^- as well as excrete the daily acid load generated from dietary protein intake. Less than half of this acid load is excreted as *titratable acids* (i.e., phosphoric and sulfuric acids); the remaining acid load is excreted as ammonium. The blood pH is determined by the balance of these processes.⁶⁴

The current mainstream understanding of the acid-base system dates back to the 1950s, when the concepts of the Henderson-Hasselbalch equation were combined with the Brønsted-Lowry theory to create a *bicarbonate ion*-centered approach.^{65,66} In the late 1970s, Stewart repackaged the pre-1950 ideas of acid-base, including the Van Slyke definition of an acid, and used physical chemistry to generate a new understanding of acid-base balance.^{65,67} The resultant strong ion difference (SID) and concentration of weak acids (particularly albumin), push HCO_3^- into a minor role as an acid-base indicator rather than as an important mechanism:

$$\text{SID} = ([\text{Na}^+] + [\text{K}^+] + [\text{Ca}^{2+}] + [\text{Mg}^{2+}]) - ([\text{Cl}^-] + [\text{lactate}])$$

Beware that SID is not the same as the anion gap (AG) and it contains [lactate], but SID does share a number of parameters with AG, and the trends of the two will often be close. The normal value for SID has not been well established, but the quoted range is 40 to 42 mEq/L. As the SID approaches zero, anions accumulate and the balance tilts toward acidity. This model makes it easier for clinicians to understand the “hyperchloremic acidosis” commonly observed following 0.9% saline administration and the systemic alkalosis of hypoalbuminemia (regarded as a weak acid).^{68,69}

Because of practical reasons, the HCO_3^- -centered approach is still commonly used over the Stewart approach to understand and manage acid-base balance.⁷⁰ The Henderson-Hasselbalch equation states that $\text{pH} = \text{pKa} + \log (\text{HCO}_3^-/\text{H}_2\text{CO}_3)$. If all constants are removed, the

BOX 36-1

Formulas for Evaluating Gas Exchange in Patients

Age-adjusted PaO_2 : Expected $\text{PaO}_2 = 0.3 (\text{age} - 25)$

Expected PaO_2 at 1 atm pressure is approximately 100 mm Hg. An approximation could be done as: Expected $\text{PaO}_2 = \text{FiO}_2 (\%) \times 5$

Alveolar-arterial gradient: $\text{AaDO}_2 = [\text{FiO}_2 \times (\text{barometric pressure} - 47)] - (\text{PaO}_2 + \text{PaCO}_2)$

Oxygenation index = $[(\text{mean airway pressure} \times \text{FiO}_2)/\text{PaO}_2] \times 100$

Dead space to tidal volume ratio: $\text{Vd/Vt} = (\text{PaCO}_2 - \text{PECO}_2)/\text{PaCO}_2$

The normal range is 20%-40%.

equation can be simplified to $\text{pH} \sim \text{HCO}_3^-/\text{PaCO}_2$. The HCO_3^- concentration is controlled mainly by the kidney and blood buffers, whereas PaCO_2 is regulated by the lungs adjusting the level of the volatile acid, H_2CO_3 , in the blood. Buffer systems can act within a fraction of a second to prevent excessive changes in pH. The respiratory system takes about 1 to 15 minutes, and the kidneys take many minutes to days to readjust the H^+ ion concentration.

The Anion Gap

According to the principle of electrochemical neutrality, total cations must equal total anions, and so when subtracting the commonly measured anions from the commonly measured cations, a fixed number should be obtained. The measured cations are in excess; mathematically, this “gap” is filled with unmeasured anions ensuring electrochemical neutrality. There is never a “real” AG because of the law of electrochemical neutrality; rather, AG is an expression of nonroutinely measured anions. AG is calculated using the following formula⁷¹:

$$\text{AG} = ([\text{Na}^+] + [\text{K}^+]) - ([\text{Cl}^-] + [\text{HCO}_3^-]) \quad (\text{normal AG} = 10 \pm 2 \text{ meq/L})$$

(Because of the low concentration of K^+ in the blood, it is not usually included in the calculation of AG.)

During critical illness, albumin typically decreases rapidly. Albumin is an important contributor of the “normal” AG; therefore, as the albumin concentration falls, it tends to reduce the size of the AG or have an alkalizing effect. Various corrections are available, of which Figge’s AG correction (AG_{corr}) is the most commonly used⁷¹:

$$\text{Albumin gap} = 40 - \text{apparent albumin (normal albumin} = 40 \text{ g/L)}$$

$$\text{AG}_{\text{corr}} = \text{AG} + (\text{albumin gap}/4)$$

STEPWISE APPROACH TO ACID-BASE DISORDERS

Step 1: Do a Comprehensive History and Physical Exam

History and physical examination can often give clues as to the underlying acid-base disorder (Table 36-1). For example, severe diarrhea could lead to loss of HCO_3^- with subsequent *non-AG metabolic acidosis*. Patients with COPD could have chronic respiratory acidosis

TABLE 36-1

Common Clinical Presentations and Associated Acid-Base Disorders

| CLINICAL PRESENTATION | ACID-BASE STATUS |
|--|---|
| Pulmonary embolism | Respiratory alkalosis |
| Shock | Lactic acidosis (metabolic) |
| Sepsis | Metabolic acidosis and respiratory alkalosis |
| Vomiting | Metabolic alkalosis |
| Diarrhea | Metabolic acidosis |
| Acute kidney injury | Metabolic acidosis |
| Cirrhosis | Respiratory alkalosis |
| Pregnancy | Respiratory alkalosis |
| Diuretics | Metabolic alkalosis unless thiazides are used |
| Chronic obstructive pulmonary disease | Respiratory acidosis |
| Diabetic ketosis | Metabolic acidosis (ketoacidosis) |
| Ethylene glycol (antifreeze) poisoning | Metabolic acidosis |
| Excessive 0.9% saline use | Metabolic non-anion gap acidosis |

because of decreased CO_2 removal with a compensatory metabolic alkalosis resulting in a normal pH.

Step 2: Order Simultaneous Arterial Blood Gas Measurement and Chemistry Profile

As mentioned in the previous section, the HCO_3^- in the ABG results is a calculated value; therefore, it is important to obtain a chemistry panel to have directly measured data. In addition, Na^+ and Cl^- will provide additional information about the volume status and SID.⁷²⁻⁷⁵

Step 3: Check the Consistency and Validity of the Results

Normal ABG results are provided in Table 36-2.

Step 4: Identify the Primary Disturbance

With the ABG results in hand, the practitioner then has to determine whether the patient is acidemic ($\text{pH} < 7.35$) or alkalemic ($\text{pH} > 7.45$) and what the primary cause is (metabolic, driven by HCO_3^- , or respiratory, driven by PaCO_2) (Table 36-3).

Step 5: Calculate the Expected Compensation

Any alteration in acid-base equilibrium sets into motion a compensatory response by either the lungs or kidneys. The compensatory response attempts to return the ratio between PaCO_2 and HCO_3^- to normal, with subsequent normalization of the pH. Compensation is usually predictable; the adaptive responses for simple acid-base disorders have been quantified experimentally⁷⁶ (Table 36-4). One has to then evaluate the compensatory responses and any secondary (uncompensated) acid-base disturbances.

Step 6: Calculate the “Gaps”

Calculate the Anion Gap

In high-AG metabolic acidosis, acid dissociates into H^+ and an unmeasured anion. H^+ is buffered by HCO_3^- , and the unmeasured anion

TABLE 36-2 Normal Acid-Base Values

| | MEAN | 1 \pm SD | 2 \pm SD |
|--------------------------|------|------------|------------|
| PaCO_2 (mm Hg) | 40 | 38-42 | 35-45 |
| pH | 7.4 | 7.38-7.42 | 7.35-7.45 |
| HCO_3^- (mEq/L) | 24 | 23-25 | 22-26 |

TABLE 36-3 Acid-Base Disorders

| DISORDER | DIAGNOSTIC CRITERIA |
|-------------------------------|--|
| Respiratory acidosis | $\text{PaCO}_2 > 45$ mm Hg |
| Respiratory alkalosis | $\text{PaCO}_2 < 35$ mm Hg |
| Acute respiratory acidosis | $\text{PaCO}_2 > 45$ mm Hg and $\text{pH} < 7.35$ |
| Chronic respiratory acidosis | $\text{PaCO}_2 > 45$ mm Hg and $\text{pH} = 7.36-7.44$ |
| Acute respiratory alkalosis | $\text{PaCO}_2 < 35$ mm Hg and $\text{pH} > 7.45$ |
| Chronic respiratory alkalosis | $\text{PaCO}_2 < 35$ mm Hg and $\text{pH} = 7.36-7.44$ |
| Acidemia | $\text{pH} < 7.35$ |
| Alkalemia | $\text{pH} > 7.45$ |
| Acidosis | $\text{HCO}_3^- < 22$ mEq/L |
| Alkalosis | $\text{HCO}_3^- > 26$ mEq/L |

TABLE 36-4 Compensation Formulas for Simple Acid-Base Disorders

| ACID-BASE DISORDER | COMPENSATION |
|-------------------------------|---|
| Metabolic acidosis | Change in $P_{aCO_2} = 1.2 \times \text{change in } HCO_3^-$ |
| Metabolic alkalosis | Change in $P_{aCO_2} = 0.6 \times \text{change in } HCO_3^-$ |
| Acute respiratory acidosis | Change in $HCO_3^- = 0.1 \times \text{change in } P_{aCO_2}$ |
| Chronic respiratory acidosis | Change in $HCO_3^- = 0.35 \times \text{change in } P_{aCO_2}$ |
| Acute respiratory alkalosis | Change in $HCO_3^- = 0.2 \times \text{change in } P_{aCO_2}$ |
| Chronic respiratory alkalosis | Change in $HCO_3^- = 0.5 \times \text{change in } P_{aCO_2}$ |

accumulates in the serum, resulting in an increase in the AG. In non-AG metabolic acidosis, H^+ is accompanied by Cl^- (a measured anion); therefore, there is no change in AG. Acid-base disorders may present as two or three coexisting disorders. It is possible for a patient to have an acid-base disorder with a normal pH, P_{aCO_2} , and HCO_3^- , and the only clue to an acid-base disorder being an increased AG. If the AG is increased by more than 5 meq/L (i.e., an AG > 15 meq/L), the patient most likely has a metabolic acidosis. Compare the fall in plasma HCO_3^- ($25 - HCO_3^-$) with the increase in plasma AG (ΔAG); these should be of similar magnitude. If there is a gross discrepancy (>5 meq/L), then a mixed disturbance is present:

The *anion gap* is calculated by subtracting the serum concentrations of Cl^- and HCO_3^- (anions) from the concentrations of sodium (cations):

$$([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-])$$

(Because of the low concentration of K^+ , it is not usually included in the calculation of AG.)

- If ΔAG is greater than the fall in HCO_3^- , this suggests that a component of the metabolic acidosis is due to HCO_3^- loss.
- If ΔAG is less than the fall in HCO_3^- , this suggests the presence of a coexistent metabolic alkalosis.

Osmolar Gap

Calculate the osmolar gap in patients with an unexplained AG metabolic acidosis to exclude ethylene glycol or methanol toxicity (Box 36-2):

The serum osmolality is calculated as:

$$2 \times (Na^+) + (Glucose)/18 + (BUN)/2.8,$$

where BUN = blood urea nitrogen (normal serum osmolality = 280–290 mOsm/kg H_2O).

The osmolar gap is defined as the difference between measured and calculated osmolality as

$$\text{Osmolar gap} = \text{Osmolality}_{\text{measured}} - \text{Osmolality}_{\text{calculated}} \\ (\text{normal} = < 10 \text{ mOsm/kg } H_2O)$$

COMMON ACID-BASE DISTURBANCES IN THE ICU

Metabolic Acidosis

The rate and degree of metabolic acidosis is mainly dependent on the underlying cause and the rapidity with which the condition develops. An acute, severe metabolic acidosis results in myocardial depression with a reduced cardiac output, decreased blood pressure, and decreased hepatic and renal blood flow; the cardiovascular system also becomes less responsive to vasopressor agents.⁷⁷ Reentrant arrhythmias and a reduced ventricular fibrillation threshold can occur.⁷⁸

The acute correction of metabolic acidosis has been a standard of care for intractable metabolic acidosis during acute coronary events. However, clinical trials have not shown improved outcomes, and acute

TABLE 36-5 Causes of Metabolic Acidosis

| INCREASED ANION GAP | NORMAL ANION GAP |
|----------------------|-----------------------|
| Acute kidney injury | Hypokalemic acidosis |
| Rhabdomyolysis | Hyperkalemic acidosis |
| Ketoacidosis | |
| Lactic acidosis | |
| Toxins: 5-oxoproline | |
| Beriberi | |

| Mannitol | Sorbitol |
| Paraldehyde | Acetone |

correction can produce paradoxical central nervous system acidosis, which has led to its removal from advanced cardiac life support algorithms.^{79–81}

Metabolic acidosis in the critically ill patient requires an aggressive approach to the diagnosis and management of the underlying cause(s) (Fig. 36-2 and Table 36-5). In most patients, the cause(s) are clinically obvious, with lactic acidosis (tissue hypoxia or sepsis), ketoacidosis, and acute kidney injury (AKI) being the most common causes.^{82–84} In patients with an unexplained AG metabolic acidosis, drugs such as salicylates, methanol, or ethylene glycol toxicity should always be considered.^{85,86} Accumulation of 5-oxoproline related to the use of acetaminophen is a rare cause of AG metabolic acidosis.⁸⁷ Long-term use of lorazepam can result in the accumulation of its vehicle, propylene glycol, resulting in worsening AKI, metabolic acidosis, and altered mental status.^{88,89} Propylene glycol toxicity is typically observed after prolonged (>7 days), high-dose (average of 14 mg/h), continuous lorazepam infusion and can be recognized by an increased osmolal gap.⁹⁰ Similarly, first reported in children and then recognized also in adults, prolonged high-dose propofol (>100 $\mu\text{g/kg/min}$) is occasionally associated with the “propofol infusion syndrome.” This is characterized by rhabdomyolysis, metabolic acidosis, and renal and cardiac failure, requiring vigilance, early cessation of propofol, and use of an alternative sedative.^{91,92} It has been suggested that frequent assessment of creatinine kinase or a lipid panel would alert clinicians to impending propofol infusion syndrome.⁹³

The prognosis is related to the underlying disorder causing the acidosis. In almost all circumstances, the treatment of a metabolic acidosis involves treating the underlying disorder. Except in specific circumstances, there is no scientific evidence to support treating a metabolic or respiratory acidosis with sodium bicarbonate.⁹⁴ Furthermore, it is the intracellular pH that determines cellular function. The intracellular buffering system, including proteins, is much more effective than extracellular buffers in restoring pH to normal.^{95,96} Consequently, patients have tolerated a pH as low as 7.0 during sustained hypercapnia, without obvious adverse effects. Paradoxically, sodium bicarbonate can decrease intracellular pH in circumstances where CO_2 elimination is fixed. In addition, infusion of bicarbonate can lead to a variety of problems in patients with acidosis, including fluid overload, hypernatremia, and postrecovery metabolic alkalosis. Furthermore, studies in both animals and humans suggest that alkali therapy may only transiently raise the plasma HCO_3^- concentration. This finding appears to be related in part to the CO_2 generated as the administered bicarbonate buffers excess H^+ ions. Unless the minute ventilation is increased in ventilated patients, CO_2 elimination will not increase and

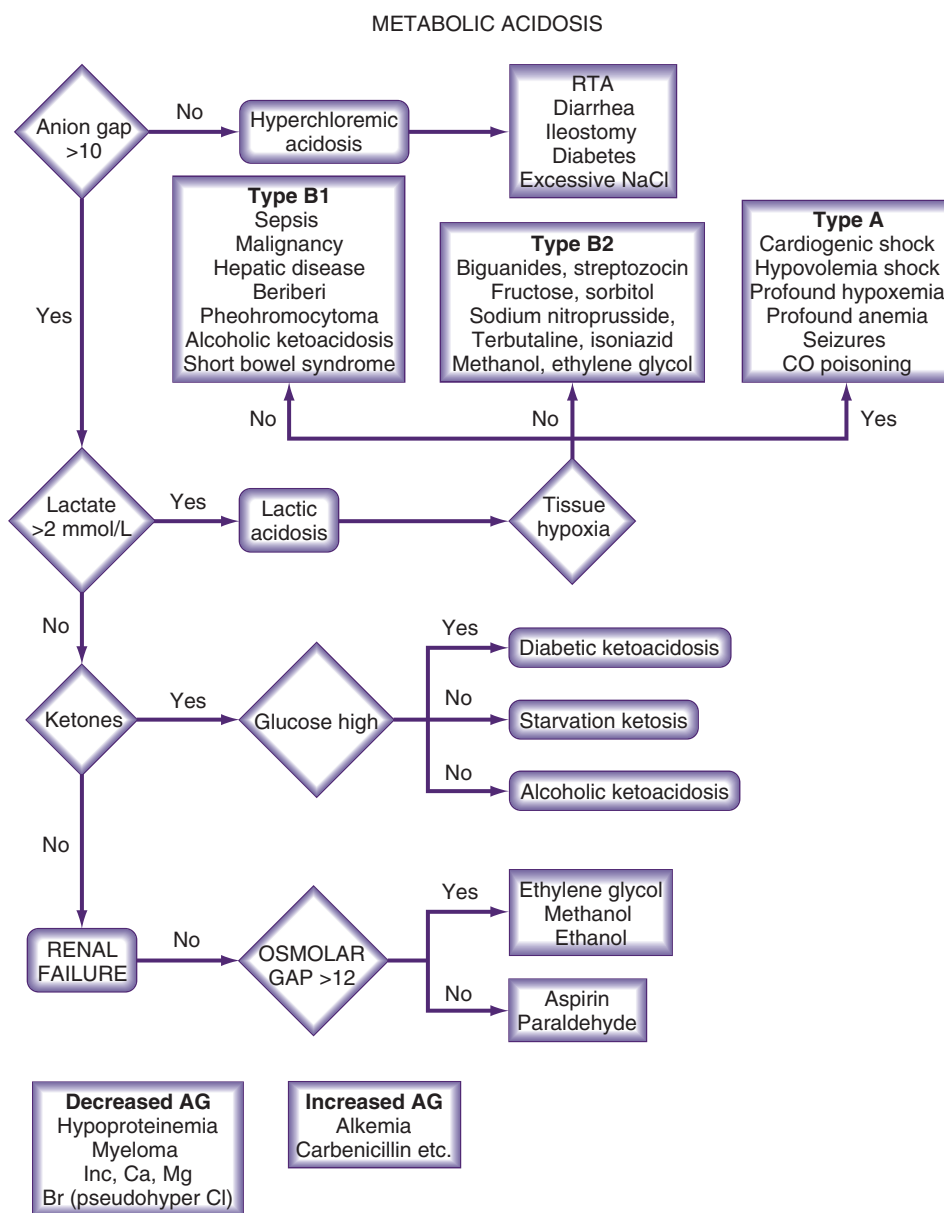

FIGURE 36-2 ■ Flowchart for diagnosing metabolic acidosis.

paradoxically will worsen the intracellular acidosis. Currently, there are no data to support the use of bicarbonate in patients with lactic acidosis.^{94,97}

Sodium bicarbonate is frequently administered to “correct the acidosis” in patients with diabetic ketoacidosis (DKA). However, bicarbonate has been demonstrated to paradoxically increase ketone and lactate production.⁹⁸ Studies have demonstrated an increase in acetoacetate levels during alkali administration, followed by an increase in 3-hydroxybutyrate levels after its completion.^{98,99} In pediatric patients, treatment with sodium bicarbonate prolongs hospitalization.¹⁰⁰ In addition, bicarbonate may decrease cerebrospinal fluid pH, as the increased CO₂ produced by buffering acid crosses the blood-brain barrier, combines with H₂O₂, and regenerates H⁺. Therefore, the consensus is that adjunctive sodium bicarbonate is unnecessary and potentially disadvantageous in severe DKA.⁷⁹

Bicarbonate is considered life saving in patients with severe ethylene glycol and methanol toxicity. In hyperchloremic acidosis, endogenous regeneration of HCO₃⁻ cannot occur (HCO₃⁻ has been lost rather than buffered). Therefore, even if the cause of the acidosis can

be reversed, exogenous alkali is often required for prompt attenuation of *severe acidemia*. Bicarbonate therapy is, therefore, indicated in patients with severe *hyperchloremic acidosis* when the pH is <7.2; this includes patients with severe diarrhea, high-output fistulas, and renal tubular acidosis. To prevent hypernatremia, we suggest that 3 × 50 mL ampules of NaHCO₃⁻ (each containing 50 mmol of NaHCO₃⁻) be added to 1 L of 5% dextrose water and infused at a rate of 100 to 200 mL/h.

Lactic Acidosis

Lactate is a by-product of pyruvate, which is produced by lactate dehydrogenase (LDH). Either in hypoxia or during sepsis, lactic acid is preferentially produced. Lactic acid, like most substances with a pKa <4 (pKa 3.78), circulates almost entirely at physiologic pH as the freely dissociated anion, lactate (i.e., it releases its proton), strongly favoring the right side of the equation:

Hyperlactatemia refers to an elevated plasma concentration of lactate anions. In clinical practice, *lactic acidemia* is defined as a pH < 7.35, with a lactate concentration greater than 4 mmol/L. Lactic acidemia typically develops as a result of endogenously produced lactic acid, with lactate being measured as the dissociated base. During critical illness, the source of lactate is often believed to be ischemic tissues undergoing anaerobic metabolism, such as the gut and muscle. In addition to ischemia, the Warburg effect with dysregulated glycolysis is a major nonischemic cause of lactatemia.^{101,102} Furthermore, it should be noted that both the pH and AG are insensitive markers of an elevated lactate; patients with an elevated lactate may have a normal pH and AG.¹⁰³

D-Lactic Acidosis

Certain bacteria and viruses in the gastrointestinal tract may convert carbohydrates into organic acids or promote LDH activity.^{104,105} The two factors that make this possible are slow gastrointestinal transit (e.g., blind loops, obstruction) and a change of the normal flora (usually with antibiotic therapy).¹⁰⁶ The most prevalent organic acid is d-lactic acid. Since humans metabolize this isomer more slowly than l-lactate, and production rates can be very rapid, life-threatening acidosis can be produced.¹⁰⁷ The usual laboratory test for lactate is specific for the l-lactate isomer. Therefore, to confirm the diagnosis, plasma or urine d-lactate levels must be specifically requested. Urinary d-lactate is more easily tested.¹⁰⁸

Metabolic Alkalosis

Metabolic alkalosis is a common acid-base disturbance in ICU patients, characterized by an elevated serum pH (>7.45) secondary to plasma HCO_3^- retention. Metabolic alkalosis is usually the result of several therapeutic interventions in critically ill patients (Table 36-6). Nasogastric drainage, diuretic-induced intravascular volume depletion, hypokalemia, and use of corticosteroids are common causes of metabolic alkalosis in these patients. In addition, citrate in transfused blood is metabolized to HCO_3^- , which may compound the metabolic alkalosis. Overventilation in patients with type II respiratory failure may result in a posthypercapnic metabolic alkalosis. In many patients, the events that generated the metabolic alkalosis may not be present at the time of diagnosis.

Metabolic alkalosis may have adverse effects on cardiovascular, pulmonary, and metabolic function. It can decrease cardiac output, depress central ventilation, shift the oxyhemoglobin saturation curve to the left (thereby decreasing offloading of Hb-bound O_2), worsen hypokalemia and hypophosphatemia, and negatively affect the ability

to wean patients from mechanical ventilation. Increasing serum pH has been shown to correlate with ICU mortality. Correction of metabolic alkalosis has been shown to increase minute ventilation, PaO_2 , and mixed venous oxygen tension (SvO_2) and to decrease O_2 consumption. It is, therefore, important to correct metabolic alkalosis in all critically ill patients. In the case of cardiac arrest, it is also challenging to correct metabolic alkalosis in a rapid fashion.¹⁰⁹⁻¹¹¹

The first therapeutic maneuver in patients with a metabolic alkalosis is to replace any volume deficit with normal saline (0.9% NaCl) and correct electrolyte deficiencies. Aggressive potassium supplementation is warranted to achieve a serum $\text{K}^+ > 4.5$ mEq/L. If these interventions fail, ammonium chloride, hydrochloric acid, or arginine hydrochloride may be given.^{111,112} The disadvantage of these solutions is that they are difficult to use and require the administration of a large volume of hypotonic fluid. Extravasation of hydrochloric acid (even at 20-25 mmol/h) may result in severe tissue necrosis, which mandates that it be administered through a well-functioning central line. Acetazolamide is a carbonic anhydrase inhibitor promoting the renal excretion of HCO_3^- and has been demonstrated to be effective in treating metabolic alkalosis in ICU patients. A single dose of 500 mg is recommended. The onset of action is within 1.5 hours, with a duration of approximately 24 hours. Doses may be repeated.^{111,113-115}

VENOUS BLOOD GAS ANALYSIS

There is a strong correlation between arterial and venous blood pH and HCO_3^- levels in patients with DKA and uremia.^{114,115} In published studies, the difference between arterial and venous pH varied from 0.04 to 0.05, and the difference in bicarbonate levels varied from -1.72 to 1.88. However, the correlation between arterial and venous PCO_2 was relatively poor.¹¹⁶⁻¹¹⁸ Actually, this difference may be used to evaluate the adequacy of O_2 availability to the tissues (see below). Similarly, an excellent correlation has been demonstrated between mixed venous pH and HCO_3^- with arterial pH and HCO_3^- in critically ill patients.^{119,120} Yet, in shock states this does not hold true; the correlation between arterial and venous pH, HCO_3^- , and PCO_2 is poor.^{121,122} During cardiopulmonary resuscitation, for example, arterial blood pH was 7.41, while mixed venous blood pH was 7.15; the corresponding values for PCO_2 were 32 mm Hg and 74 mm Hg, respectively.^{123,124}

Once shock is resolved, ABG testing would not be necessary in patients without hypercarbia. Pulse oximetry and venous blood gas analysis would be enough to make clinical decisions. Furthermore, a venous blood gas can be useful to screen for arterial hypercarbia, as a venous $\text{PCO}_2 > 45$ mm Hg is highly predictive of arterial hypercarbia.¹²⁵

Mixed Venous/Central Venous Oxygen Saturation

Monitoring SvO_2 has been used as a surrogate for determining the balance between systemic O_2 delivery and consumption during the treatment of critically ill patients.¹²⁶ An $\text{SvO}_2 < 65\%$ is indicative of inadequate O_2 delivery. However, a mixed venous blood sample needs to be collected from the distal port of a pulmonary artery catheter, an invasive device that has not been shown to improve patient outcome. Therefore, most clinicians use as a surrogate the central venous oxygen saturation (ScvO_2).^{127,128}

There are multiple reasons why ScvO_2 and SvO_2 can differ. First of all, the vena caval blood streams into the right atrium and ventricle, and complete mixing only occurs during ventricular contraction. In addition, blood from the coronary sinus and Thebesian veins results in further discrepancies.^{129,130} Thus, SvO_2 is a better indicator of whole body balance of oxygen supply and demand, whereas ScvO_2 reflects changes in the upper body. In hemodynamically stable, healthy patients, ScvO_2 is usually 2% to 5% less than SvO_2 because of the high O_2 content of effluent venous blood from the kidneys.¹³¹ This changes during shock as blood is redistributed to the upper body at the expense of the splanchnic and renal circulations. In shock, ScvO_2 may exceed

TABLE 36-6 Causes of Metabolic Alkalosis

| LOW URINE CHLORIDE (VOLUME- OR SALINE- RESPONSIVE) | HIGH URINE CHLORIDE WITH HYPERTENSION |
|--|--|
| Gastric volume loss | Primary and secondary hyperaldosteronism |
| Diuretics | Apparent mineralocorticoid excess |
| Posthypercapnia | Liddle's syndrome (autosomal dominant, pseudoaldosteronism) |
| Villous adenoma (rare) | Conn's syndrome |
| Cystic fibrosis (if there has been excessive sweating) | Cushing disease |
| HIGH URINE CHLORIDE WITHOUT HYPERTENSION | |
| Bartter syndrome | |
| Gitelman syndrome (autosomal recessive hypokalemic metabolic alkalosis) | |
| Excessive bicarbonate administration | |

SvO₂ by up to 20%.¹³² This was also true for patients with cardiogenic, septic, and hemorrhagic shock.¹³³ Therefore, one has to assess these saturation values within the context of the clinical scenario.^{128,132,134-138} In patients with sepsis and liver failure, a low ScvO₂/SvO₂ is usually indicative of decreased cardiac output, and normal values do not necessarily exclude resuscitation or tissue oxygenation.¹³⁹⁻¹⁴¹ In liver failure, all pathologic collaterals may result in "arterialization" of the venous blood. In addition, cytopathic hypoxia may further decrease O₂ uptake and result in a "spuriously high" ScvO₂.¹⁴² Interestingly, patients dying of both sepsis and liver failure usually have a high ScvO₂/SvO₂.¹⁴³ In a recent goal-directed sepsis study, the mean ScvO₂ was 74% at enrollment, and less than 10% of patients required specific interventions to achieve values >70%.¹⁴⁴

In addition, a high mixed venous-to-arterial PCO₂ gradient is a predictor of decreased cardiac output and global tissue ischemia.¹⁴⁵⁻¹⁴⁷ This observation has been confirmed by Weil et al. and Androgué et al., who demonstrated that a high mixed venous-to-arterial PCO₂ gradient is a sensitive marker of global tissue ischemia during cardiogenic and septic shock.^{124,148-151} Recent work suggests that a central venous-to-arterial PCO₂ gradient >6 mm Hg is a reliable indicator of successful resuscitation in septic shock.¹⁵²

In summary, as a rule of thumb, venous blood gases cannot be substituted for ABG analysis in hemodynamically unstable patients and those with complex acid-base disorders. In these situations, both arterial and mixed venous/central venous blood gas analysis provides useful information.

KEY POINTS

1. Arterial blood gas (ABG) analysis is the gold standard for assessing oxygenation, ventilation, and acid-base status in critically ill patients, as long as it is obtained and interpreted within the clinical context.
2. Pulse oximetry can provide a surrogate measure of arterial oxygen tension (PaO₂). Venous pH and bicarbonate (HCO₃⁻) allow for an estimation of arterial pH and HCO₃⁻ in hemodynamically stable patients, yet one needs to be cautious during shock states. Venous carbon dioxide tension (PCO₂) is a poor proxy for arterial PCO₂. Venous blood gas analysis can be useful to screen for arterial hypercarbia, with a venous PCO₂ level > 45 mm Hg being highly predictive of arterial hypercarbia.
3. The indications for ABG sampling have not been well defined; however, an ABG should generally be performed on admission to the ICU, following endotracheal intubation, and as the clinical context changes.
4. ABG sampling does not have to be performed after each ventilator change or after each step during weaning from the ventilator.
5. Metabolic acidosis is serious; its etiology has to be determined and treatment initiated immediately.
6. In most clinical situations, sodium bicarbonate administration is of no therapeutic utility during metabolic acidosis.
7. In patients with a metabolic alkalosis, correct the volume and potassium deficit first, then initiate an acetazolamide and/or hydrogen chloride infusion.
8. Central venous oxygen saturation (S_{cv}O₂) and the central venous-to-arterial PCO₂ gap have utility in assessing the adequacy of resuscitation and oxygen delivery.

ANNOTATED REFERENCES

TRADITIONAL VS. NEW PERSPECTIVE ON ACID-BASE BALANCE

While the bedside clinician needs a handy tool to understand acid-base balance to help diagnose and manage patients appropriately, academic disagreements still exist regarding the topic of acid-base balance. In summary, the traditional approach suggests that the activity of H⁺ in a biological space is determined by the mass balance of H⁺, proton transfer reactions via proton donors (weak acids) and proton acceptors (weak bases), and the mass balance of proton donors and proton acceptors. (Arrhenius, Sorenson, Henderson, Hasselbalch, Bronsted and Lowry, Van Slyke, Lewis, Severinghaus, Astrup, Siggard-Andersen, Schwartz, and Relman).

In 1978, Stewart questioned the traditional dogma by proposing that a complex mixture of ions (Na⁺, K⁺, and Ca²⁺) regulate the activity of H⁺ over the physiologic pH range, nonvolatile proton donors and acceptors (albumin, phosphate, Hb, and metabolizable organic compounds) transfer H⁺ within the physiologic pH range, and the volatile bicarbonate-CO₂ buffer system is composed of CO₂, HCO₃⁻, H₂CO₃, and CO₃²⁻. The following are useful articles from the literature on the topic. Elbers PW, Van Regenmortel N, Gatz R. Over ten thousand cases and counting: acidbase.org is serving the critical care community. *Anaesthesiol Intensive Ther* 2015;47(5):441-448.

A new reference of a handy online web tool to help understand acid-base balance and a freely available textbook of Dr. Stewart. The web tool helps calculate the strong ion difference.

Kurtz I, Kraut J, Ornekian V, Nguyen MK. Acid-base analysis: a critique of the Stewart and bicarbonate-centered approaches. *Am J Physiol Renal Physiol* 2008;294(5):F1009-F1031.

The authors support the idea that the H⁺/HCO₃⁻ approach based on the Henderson-Hasselbalch equation is mechanistically more robust than the Stewart or strong ion approach. Accordingly, CO₂/HCO₃⁻ is useful in the hands of clinicians to help approach all acid-base derangements seen clinically; however, it is qualitative in nature and cannot quantify acid or base loads that result in metabolic acid-base disorders, despite the concomitant use of base excess information. These drawbacks led to the argument for a more quantitative measurement, the Stewart approach. However, both are "equilibrium equations" and have similar predictive value for clinical acid-base disorders, supporting the authors' opinion that their favorite approach is the Henderson-Hasselbalch equation.

OXYGEN TENSION: FROM A GLOBAL PERSPECTIVE TO A REGIONAL ASSESSMENT

The concept of partial pressure of oxygen measured in arterial blood gas analyses could be easily applied to oxygen tension measurements in regional perfusion. A recent work on brain tissue oxygen tension is relevant to the intensivist.

Rosenthal G, Hemphill JC 3rd, Sorani M, et al. Brain tissue oxygen tension is more indicative of oxygen diffusion than oxygen delivery and metabolism in patients with traumatic brain injury. *Crit Care Med* 2008;36(6):1917-1924.

The specific determinants of low brain tissue oxygen tension (P_{bt}O₂) following severe traumatic brain injury remain poorly defined; specifically, the question is whether P_{bt}O₂ reflects cerebral oxygen diffusion or cerebral oxygen delivery and metabolism. This group measured P_{bt}O₂ directly, as well as cerebral venous blood gases from a jugular bulb venous catheter. Following multiple logistic regression modeling, a strong association was detected between P_{bt}O₂ and diffusion of dissolved plasma oxygen across the blood-brain barrier, suggesting that P_{bt}O₂ reflects cerebral blood flow and the cerebral arteriovenous O₂ difference.

OTHER USES OF CO₂ MEASUREMENTS: EVIDENCE SUGGESTING THAT CO₂ COULD BE USED AS AN ENDPOINT FOR RESUSCITATION IN SEPSIS

Guzman JA, Dikin MS, Kruse JA. Lingual, splanchnic, and systemic hemodynamic and carbon dioxide tension changes during endotoxic shock and resuscitation. *J Appl Physiol* (1985) 2005;98(1):108-113.

The authors studied sublingual and intestinal mucosal blood flow and P_{co2} in a canine model of lipopolysaccharide-induced circulatory shock and resuscitation. Shock induced increased sublingual and splanchnic PCO₂, and the levels were nearly reversed after fluid resuscitation while systemic hypotension persisted. Changes in sublingual and splanchnic PCO₂ paralleled gastric and intestinal PCO₂ changes during shock but not during resuscitation. This and other work suggest the utility of PCO₂ in estimating tissue perfusion.

Mesquida J, Saludes P, Gruartmoner G, et al. Central venous-to-arterial carbon dioxide difference combined with arterial-to-venous oxygen content difference is associated with lactate evolution in the hemodynamic resuscitation process in early septic shock. *Critical Care* 2015;19:126.

Since normal or high central venous oxygen saturation (S_{cv}O₂) values cannot discriminate whether tissue perfusion is adequate, other markers of tissue hypoxia are required. The authors studied the ratio of central venous-to-arterial carbon dioxide difference (P_{cv}aCO₂ gap) to the arterial-venous oxygen content difference (C_{av}O₂) ratio to predict lactate evolution in septic shock. A high P_{cv}aCO₂/C_{av}O₂ ratio had a high predictive power for no improvement in lactate clearance. The receiver operating characteristic curve had an area under the curve of 0.82, and when the P_{cv}aCO₂/C_{av}O₂ ratio was set at 1.4 mm Hg · dL/mL O₂, it carried a sensitivity of 0.80 and specificity of 0.75 for lactate improvement. This ratio and PCO₂ could be used for predicting outcomes from sepsis.

Tracheal intubation is a common, high-risk procedure. Risks associated with intubation in critically ill patients remain high and include prolonged hypoxemia, hemodynamic instability, cardiac arrest, and death. Over the past decade, significant improvements in patient safety have been reported for this procedure by employing skilled operators, a systematic approach to airway management, and advanced airway tools. The goal of this chapter is to provide a common, systematic approach using best evidence to maximize the success and safety of tracheal intubation in the intensive care unit (ICU).

AIRWAY MANAGEMENT CHALLENGES IN THE CRITICALLY ILL

Reported complication rates from tracheal intubation in the critically ill range from 4.2% to 22% and remain unacceptably high in comparison to operating room procedures.¹⁻⁵ Emergent ICU airway management cases leave little time to perform a thorough airway assessment and less time to plan when high-risk anatomic features are present. Cardiopulmonary disease makes preoxygenation more difficult, providing less apneic time during intubation before hypoxemia develops.⁶ Hemodynamic instability can limit the choice and dose of induction and paralytic agents that, combined with upper airway secretions, edema, and loss of muscle tone, can decrease glottic visualization. Other coexisting comorbidities, including obesity, increased intracranial pressure, and acute coronary syndrome can further complicate management of the critically ill during tracheal intubation.

TRAINING

Current airway management training is highly variable, even among anesthesia providers.⁷⁻¹⁰ A recent meta-analysis suggested that the level of training, as opposed to specialty, was the key factor for optimizing proper airway management.^{11,12} The appropriate volume and scope of airway training required, however, remains a topic in need of further research. Novices can obtain reasonable competence with direct laryngoscopy after 30 to 50 cases and may accelerate their skills using video-assisted instruction, but performance continues to improve even after 100 intubations.¹³⁻¹⁵ Box 37-1 provides a suggested list of airway management topics for training, but these recommendations are expert opinion only.¹⁶ The development of a vast array of advanced airway management devices has only complicated efforts to standardize training and approaches to ICU airway management. In a national survey of 180 American ICU and anesthesiology directors, only 70% had a difficult airway cart in their ICU, and 60% of the respondents reported that they had not been trained in the use of such equipment.¹⁷

INDICATIONS FOR TRACHEAL INTUBATION

Tracheal intubation is most commonly performed in critically ill patients with active or impending respiratory failure due to inadequate oxygenation and/or ventilation or for airway protection due to an inability to maintain a patent airway. Artificial airways can also facilitate secretion clearance and hyperventilation in the setting of an intracerebral herniation syndrome and can enhance the safe performance of procedures requiring conscious sedation in the setting of significant cardiopulmonary disease.

MAXIMIZING PATIENT SAFETY DURING TRACHEAL INTUBATION

The American Society of Anesthesiologists recommends that an airway assessment be performed before all intubations and emphasizes a systematic approach that maximizes oxygen delivery and considers an awake procedure, a variety of noninvasive techniques, and preservation of spontaneous ventilation.¹⁸ Other recent studies have also underlined the importance of a systematic approach to airway assessment, patient and equipment preparation, and procedure planning to maximize intubation success. Jaber et al. demonstrated that implementation of a protocolized ICU intubation bundle (Box 37-2) reduced complications by 25%.¹⁹ Improved patient safety and reduced need for emergent surgical airways have been achieved through implementation of a standardized, team-based approach that includes proactive identification of patients with known difficult airways, ready availability of advanced airway equipment, simulation-based airway skills and teamwork training, a mandatory bedside procedure checklist, and post-event debriefs.^{20,21} The APPROACH mnemonic (Box 37-3) is one structured checklist tool to ensure that these standardized interventions are consistently performed.²²

Airway Assessment

Common methods of airway assessment are limited in their ability to correctly identify difficult airways (positive predictive value, 4%-27%).^{23,24} The MACOCHA score, a seven-item validated prediction tool for the critically ill, is perhaps the most valuable tool for identifying high-risk patients.^{25,26}

Preoxygenation

Adequate preoxygenation is essential to maximize the time for intubation attempts. Use of a resuscitation bag, oral or nasal airway, positive end-expiratory pressure (PEEP) valve, high-flow nasal cannula system, or noninvasive positive pressure ventilation (NIPPV) can help improve and sustain patient oxygen saturation when standard bag-valve-mask ventilation proves challenging.^{27,28} Head of bed elevation may be particularly helpful to sustain apneic normoxia in patients with obesity, atelectasis, or reduced lung compliance, but apneic oxygenation using a nasal cannula during intubation was recently shown not to be beneficial.²⁹⁻³²

Preparation and Teamwork

The Fourth National Audit Project of the Royal College of Anaesthetists and Difficult Airway Society (NAP4) found that preparation, equipment, and communication errors were the most common causes of complications during airway management in ICUs and emergency departments in the United Kingdom.³³ These data underline the importance of deliberate planning and preparation to maximize patient safety and procedure success.

Patient positioning is especially important in ICU patients. Common methods include placing the patient in a supine position, moving them close to the head of the bed, and raising their head to or just below the level of the operator's xiphoid process. Provided there is no concern for neck injury, the patient's head is placed in a sniffing

BOX 37-1 Fundamental Airway Knowledge and Skills

Face mask ventilation, airway positioning
Laryngeal mask airway (LMA, including intubating devices)
Oral endotracheal intubation (direct laryngoscopy, DL)
Simple maneuvers (positioning, BURP*) to improve DL
Use of stylet, gum elastic bougie
Rapid sequence induction
Fiberoptic intubation via conduit (oropharyngeal airway, LMA)
Percutaneous cricothyrotomy

*BURP, Backwards, Upwards, and Rightwards Positioning.

BOX 37-2 ICU Intubation Bundle Used in a Large Multicenter Study to Improve Patient Outcomes

PREINTUBATION

1. Presence of two operators
2. Fluid loading (isotonic saline [500 mL] or hetastarch [250 mL]) in the absence of cardiogenic pulmonary edema
3. Preparation of long-term sedation
4. Preoxygenation for 3 min with NIPPV in case of acute respiratory failure (FiO_2 100%, pressure support ventilation level between 5 and 15 cm H_2O to obtain an expiratory tidal volume between 6 and 8 mL/kg and PEEP of 5 cm H_2O)

DURING INTUBATION

5. Rapid sequence induction: etomidate (0.2–0.3 mg/kg) or ketamine (1.5–3 mg/kg) combined with succinylcholine (1–1.5 mg/kg) in the absence of allergy, hyperkalemia, severe acidosis, acute or chronic neuromuscular disease, burn patients for more than 48 hours, and major crush injury
6. Sellick maneuver

POSTINTUBATION

7. Immediate confirmation of tube placement by capnography
8. Norepinephrine if diastolic blood pressure remains <35 mm Hg
9. Initiate long-term sedation
10. Initial “protective ventilation”: tidal volume 6–8 mL/kg of ideal body weight for a plateau pressure <30 cm H_2O

NIPPV, non-invasive positive pressure ventilation; PEEP, positive end expiratory pressure; FiO_2 , inspired oxygen fraction.

From Jaber S, Jung B, Corne P, Sebbane M, Muller L, Chanques G, et al. An intervention to decrease complications related to endotracheal intubation in the intensive care unit: a prospective, multiple-center study. *Intensive Care Med* 2010;36:248–255.

position to align the oral, pharyngeal, and laryngeal axes for traditional direct laryngoscopy attempts. A rolled towel under the shoulders and a flat towel underneath the head can also help with alignment. Patients with known or suspected cervical injury should receive inline stabilization of the head and neck, which remain in a neutral position during intubation attempts.

Crew resource management principles important for an efficient airway management team include explicit role assignments, closed loop communication, and standardized equipment and medication preparation and positioning. Clear articulation of the primary and backup airway management plans and discrete oxygen cutoffs (which should prompt termination of intubation efforts and resumption of bag-valve-mask ventilation) provide shared situational awareness and guidance to maintain quality control and safety throughout the procedure. An empiric crystalloid bolus in the absence of decompensated heart failure and readily available vasopressors also reduce the risk of hypotension during intubation.¹⁹

Airway Pharmacology

Rapid sequence intubation is the standard of care in the emergency department due to its high rate of success.³⁴ Medication

BOX 37-3 The ACCP APPROACH to Airway Management

Assess the airway—it's all in your **HAND**

History of difficult intubation

Anatomic considerations

3-3-2 rule

Modified Mallampati Classification

Other risk factors for airway distortion, obstruction

Neck mobility

Difficult airway should be considered if concerns with any of the factors above

Preoxygenate using 100% oxygen, bag-valve-mask with PEEP valve

Prepare

Patient: Sniffing position, headboard off and patient head just below the intubator's xiphoid process

Medications: Free-flowing IV, premedication, induction, paralytic, and vasopressor agents

Right side: Suction, endotracheal tube with stylet and syringe attached

Left side: Laryngoscope handle, blades, oral and nasal airways, end-tidal CO_2 detector

Review team member roles, primary and backup intubation plans

Oxygen cutoffs: Identify signals to abort, reinstate bag-valve-mask ventilation

Administer medication, if indicated

Confirm endotracheal tube placement using two indicators (including end-tidal CO_2)

Hold endotracheal tube until secured

Myopathy

Crush injury

Severe burns (>24 hours)

Prolonged immobility

administration in critically ill patients is more variable because of differences in provider comfort, hemodynamics, and concern for airway failure. Outside of a pulseless or unresponsive patient, however, selecting and preparing appropriate medications should be a routine part of intubation preparation and planning. Common agents, indications, and doses are summarized in [Table 37-1](#).³⁵ Drugs administered before induction are particularly useful in the setting of severe exacerbations of obstructive lung disease and significant intraocular or intracranial hypertension. Initial induction agent doses should be reduced by 25% to 50% in the elderly and in patients with hypotension, hypovolemia, or significantly impaired cardiac function. Propofol provides the best glottic visualization at full induction doses but causes significant hypotension. Etomidate has less associated hypotension and myocardial depression. It reduces adrenal steroidogenesis, but single doses do not appear to increase mortality even in septic patients.³⁶ Ketamine increases heart rate, blood pressure, and cardiac output and has been shown to provide similar intubating conditions and outcomes to etomidate in a large, prospective randomized trial.³⁷ Its use in the setting of increased intracranial pressure (ICP) is controversial.^{38,39}

The combination of an induction agent such as propofol with a paralytic has been shown to produce optimal intubating conditions.⁴⁰ The most commonly used agent is succinylcholine, a depolarizing muscle relaxant with a rapid onset of action and very short duration. In situations where succinylcholine may be considered unsafe ([Box 37-4](#)), rocuronium or atracurium will provide a similar onset of action but a much longer duration of paralysis. Use of rapid sequence intubation in the ICU remains controversial, but growing evidence suggests it is safe and effective when employed thoughtfully by an experienced operator.⁴¹

TABLE 37-1 Common Medications Used During Tracheal Intubation

| PREINDUCTION MEDICATIONS | | | | |
|--------------------------|--|--|---------------|---|
| DRUG | DOSE, COMMON INDICATIONS | CAUTIONS | | |
| Fentanyl | 2-3 micrograms/kg IV, 1-2 mins CAD, aneurysm, increased ICP | Hypotension Masseter, chest wall rigidity | | |
| Esmolol | 2-3 mg/kg IV Neurosurgery, head injury | Bradycardia Hypotension, bronchospasm | | |
| Lidocaine | 1.5 mg/kg IV, 2-3 min Asthma, COPD, increased ICP | Hypotension | | |
| INDUCTION MEDICATIONS | | | | |
| AGENT | ONSET (SECONDS) | DURATION (MINUTES) | DOSE | |
| Propofol | 9-50 | 3-10 | 0.5-2 mg/kg | |
| Etomidate | 30-60 | 3-5 | 0.2-0.3 mg/kg | |
| Ketamine | 60-120 | 5-15 | 2 mg/kg | |
| NEUROMUSCULAR BLOCKERS | | | | |
| AGENT | ONSET (SECONDS) | DURATION (MINUTES) | DOSE | OFF-LABEL DOSING |
| Succinylcholine | 30-60 | 5-15 | 1.0-1.5 mg/kg | Manufacturer's recommendation 0.6 mg/kg |
| Rocuronium | 45-60 | 45-70 | 0.6-1.2 mg/kg | |
| Atracurium | 60-90 | 35-70 | 0.4-0.5 mg/kg | |

■ INTUBATION TECHNIQUES

Recent years have seen the development of a wide array of commercially available airway equipment, with mixed availability and familiarity in many ICUs.¹⁷ Most experts recommend the selection of a limited list of airway tools most appropriate for a given ICU population to facilitate familiarity and training.

Direct Laryngoscopy

Current Macintosh and Miller blades are designed for rapid endotracheal tube placement. The Macintosh blade is broad and curved and includes a flange to displace the tongue to the left when the blade is introduced into the mouth from the right side (paraglossal approach). The blade is advanced toward midline, and the tip is directed into the vallecula once the epiglottis comes into view. Gentle blade traction will lift the epiglottis and expose the glottic aperture. The Miller blade is longer and straight with a slightly curved tip. It can be inserted using either a paraglossal or midline approach, and the distal end is used to directly lift the tip of the epiglottis. Care must be taken with both blades to apply caudal and anterior force, holding the laryngoscope handle near its base and keeping its angle less than 45 degrees to the patient to avoid dental damage. Blade sizes 3 or 4 are most appropriate for adult procedures. The broader surface of the Macintosh blade may provide better upward displacement of excess upper airway soft tissue, and the longer and narrower profile of the Miller blade may assist in the setting of narrow mouth opening or a long epiglottis. A stylet is generally used to help guide the ETT through the vocal cords and can be shaped with a distal bend to aid in tracheal placement.

Indirect Laryngoscopy Devices

Indirect laryngoscopy devices provide video or optical imaging using mirrors and prisms to improve glottic visualization in individuals in whom alignment of the airway axes is difficult. Some devices incorporate an acutely angulated blade (i.e., Glidescope, McGrath, C-Mac), while others incorporate a channel (i.e., AirTraQ, Pentax) to facilitate endotracheal tube placement through a more anterior glottis with the head in a neutral position.⁴²

Current literature suggests that indirect laryngoscopy offers little advantage in the average patient but affords high rates of intubation success in patients with difficult airway risk factors, obesity, or failed direct laryngoscopy attempts.⁴³⁻⁴⁷ This advantage does not appear to be uniform; the Airtraq optical laryngoscope, for example, has performed less favorably in difficult airways in the prehospital setting.⁴⁸ Videolaryngoscopy can also accelerate training performance with novices and provides a high rate of first-time success in the hands of less experienced intubators.⁴⁹⁻⁵¹ Each device has unique technical considerations that operators must be familiar with to maximize their potential benefit.

■ THE DIFFICULT AIRWAY

The definition of a difficult airway is the presence of clinical factors that complicate ventilation or intubation.¹⁸ The incidence of difficult airways encountered during emergent intubations is reported to be 10%.^{2,3}

The best management approach to a difficult airway in the ICU is not well studied. Until the many complex variables present in ICU airway management can be more systematically analyzed, the following suggestions represent the consensus opinion of one group of experts based on available data.⁵²

Emergency Airway Management: Extraglottic Airways and Cricothyroidotomy

Prolonged hypoxemia is the primary cause of most serious airway complications. If aggressive initial attempts to restore adequate oxygenation are not successful, early emergency airway management should be accomplished using either an extraglottic airway or cricothyroidotomy.

Extraglottic airways (EGAs, such as the Laryngeal Mask Airway and King tube) can be placed into the upper airway to reestablish adequate oxygenation and ventilation without significant technical expertise in many cases. Intubation through EGAs has proven successful following failed direct laryngoscopy and as a more rapid primary approach in patients with a predicted difficult airway.^{53,54} A number of current EGAs also provide the option of one-step intubation through

the device (Ambu Aura-i, CookGas LLC Air-Q/ILA, LMA Fastrach, and Classic Excel, i-Gel).

Surgical cricothyroidotomy is reserved for the emergency airway situation when an extraglottic airway cannot be effectively employed due to upper airway abnormalities, blood, or secretions that obviate proper placement and function. Cricothyroidotomy can be performed most rapidly using a rapid four-step technique.⁵⁵ Using a bougie through the neck incision to serve as an ETT guide has been shown to be successful even in the hands of the novice nonsurgeon.⁵⁶ A cricothyroidotomy kit that uses a Seldinger approach is also available but has been associated with longer time to placement.⁵⁷ Major complications include esophageal perforation, subcutaneous emphysema, and bleeding.

The Role of Advanced Airway Tools in Difficult Airway Management

If initial stabilization and oxygenation is possible, a rapid clinical airway assessment is essential to plan an appropriate and effective management strategy. Cooperative patients with slowly progressive respiratory failure and predicted difficult airways can be considered for awake intubation. More unstable or uncooperative patients can be managed with indirect laryngoscopy, gum elastic bougie, or an extraglottic airway.

Awake intubation provides the opportunity to preserve spontaneous respiration and prolong the available time for intubation attempts. Upright fiberoptic-assisted intubation through a Williams or Ovassapian intubating airway is a common and effective approach. Patients typically require a combination of nebulized or atomized lidocaine directed at the base of tongue and tonsillar pillars. Antisialagogues are frequently employed to aid visualization, and low-dose narcotics such as remifentanyl appear to be superior to dexmedetomidine when combined with low-dose midazolam for sedation.⁵⁸ Unfortunately, the 20-30 minutes required for appropriate airway preparation can be challenging in critical care practice, limiting broad-based application of this technique.

In the setting of a predicted difficult airway, indirect optical devices and videolaryngoscopes provide better glottic visualization and

maximize the opportunity of intubation success. In one large single institution study, a gum elastic bougie was the preferred method to successfully manage patients with incomplete glottic visualization and those for whom glottis intubation is not possible.² An intubating extraglottic airway is also an appropriate primary or rescue strategy.

CONCLUSION

Tracheal intubation in the ICU remains a high-risk procedure, and a systematic approach that emphasizes planning, preparation, and teamwork is necessary to maximize its outcome and safety. Although intensivists should maintain facility with direct laryngoscopy, there are growing data supporting the use of indirect laryngoscopy as both a primary and rescue technique in the ICU. In the setting of an emergency airway, an extraglottic airway or surgical airway should be rapidly employed. If oxygenation and ventilation can be reestablished, a wider variety of techniques can be considered. Until better evidence is available, ICU directors must apply these general principles to develop a safe and effective airway management program in their institution.

DISCLAIMER

The views expressed in this review are those of the author and do not reflect the official policy or position of the Department of the Army, Department of Defense, or the U.S. government.

KEY POINTS

1. A systematic approach that emphasizes planning, preparation, and teamwork is the best proven method to reduce risks associated with airway management in the ICU.
2. An extraglottic airway should be employed early in the patient with inadequate oxygenation and ventilation.

Tracheotomy, one of the most commonly performed procedures in critical care, involves the surgical creation of an external opening in the tracheal wall to establish a stable airway. Usually, the stoma tract is kept open by inserting a tracheostomy tube with or without a cannula. The size and type of the cannula will depend on the context of the neurologic and respiratory impairment.

Opinions differ on whether the right term for the procedure is *tracheotomy* or *tracheostomy*; *tracheostomy* will be used here and is more common in the current literature and clinical practice.

Both surgical tracheostomy and percutaneous dilational tracheostomy (PDT) are performed in critical care patients with an upper airway obstruction or prolonged endotracheal intubation to facilitate airway management during long-term ventilation, enhance patient comfort (communication and airway clearance), enhance airway security, and reduce respiratory resistance (for faster weaning from mechanical ventilation).

■ INDICATIONS

Airway access for the treatment of an upper airway obstruction or mechanical ventilation can be obtained by either orotracheal intubation (OTI) or placement of a tracheostomy tube. During ventilation in general anesthesia or episodes of acute respiratory failure, patients are usually ventilated through an orotracheal tube, which can be easily and rapidly inserted into an initial airway device. Use of OTI minimizes acute surgical complications (e.g., bleeding, nerve and posterior tracheal wall injury) and late complications (e.g., wound infection and tracheal lumen stenosis) that may develop after the tracheostomy tube placement.

The introduction of the PDT by Ciaglia in 1985 as an alternative to a surgical tracheostomy attracted interest regarding its indications.¹ Initially, PDT was reserved for patients with few risk factors and favorable neck anatomy. However, with wider use, the indications expanded and PDT largely replaced surgical procedures. During the past decade, the use of PDT has increased, as has the use of tracheostomy for prolonged ventilation or treating upper airway obstruction secondary to trauma or surgery of the face and neck region.²

Recent studies have evaluated the effects of tracheostomy on long-term outcome. Frutos-Vivar et al. showed that tracheostomy was independently related to survival in the intensive care unit.³ Even if hospital mortality was similar between patients with and without a tracheostomy, there were significant differences in where the patients were discharged from the hospital. At home, mortality doubled for patients who required tracheostomy.

Moreover, many patients with tracheostomy require long-term care facilities. Therefore, because of its invasiveness and procedural risks, tracheostomy should be considered only when prolonged mechanical ventilation is expected.

■ ADVANTAGES OF TRACHEOSTOMY

European surveys investigating the use of tracheostomy in critically ill patients reveal the heterogeneity regarding techniques, timing, operator experience, and setting.⁴ Tracheostomy offers many clinical benefits for patients with respiratory failure or those requiring prolonged mechanical ventilation or airway protection because of neurologic

dysfunction. As compared with OTI, the safe anchorage provided by the tracheostomy tube reduces the risk of dislocation and potential accidental extubation, which could turn into an emergency in ventilated patients. Moreover, since the internal cannula is not affected by head and neck movement, the occurrence of lesions due to tracheal mucosal abrasion and laryngeal damage is low.

Besides allowing for easier draining of airway secretions and facilitating pulmonary toilet and oral hygiene, tracheostomy improves patient comfort by facilitating communication with family members and nurses and by reducing salivary stagnation in the larynx and pain during swallowing. Patients can be mobilized earlier and easier, with a faster return to oral feeding, shorter residence time of the nasogastric tube,^{5,6} and reduced risk of tracheoesophageal fistula formation.

Use of a tracheostomy tube can aid in weaning from mechanical ventilation, since the direct approach to the trachea (with an internal diameter greater than for the translaryngeal approach) and the minor length and absence of multiple curves all reduce airflow resistance. Moreover, it also allows for faster resumption of autonomous respiration, with reduced use of sedative agents, fewer days on the mechanical ventilator, shorter length of stay in the intensive care unit (ICU), and reduced use of resources.^{3,7,8} Although PDT continues to gain acceptance as the method of choice, no single technique has been shown to be superior to another in all clinical situations. Furthermore, PDT has a steep learning curve and requires mastery of procedural skills and extensive expertise.

■ COMPLICATIONS

Complications arising from tracheostomy maneuvers based on the time between the procedure and the onset of symptoms can be classified as intraoperative and postoperative (early and late complications, respectively). The frequency and severity of complications depend on tracheostomy technique, operator experience, patient anatomy, and pathophysiologic factors related to the degree of organ dysfunction, especially respiratory and coagulation deficits.

Procedure-related complications include desaturation and difficult cannula placement due to acute tracheostomy tube occlusion (generally because of the formation of a blood clot or mucous plug) or tube insertion into the wrong tract. Other early complications include hemorrhage, with bleeding controlled by local pressure or requiring exploration (with the conversion from PDT to another dilational technique or surgery in some cases) or desaturation due to subcutaneous emphysema with or without evidence of pneumothorax. Patients with severe bleeding should undergo a bronchoscopy for suspected tracheoesophageal fistula, but this complication is normally characteristic of late complications.

Common adverse events in the postoperative period or later include slight bleeding, controlled by local pressure, accidental cannula removal and the displacement (dislodged tracheal tubes within 7 days of insertion should be replaced with a tube the same size or smaller), and airway obstruction due to granuloma formation or infection or inflammation of the stoma.

Numerous uncontrolled case series have reported PDT complications, but there are few prospective comparative studies of complications associated with PDT and surgical tracheostomy or among different PDT methods. A meta-analysis by Freeman et al. found that

as compared with surgical tracheostomy, Ciaglia's and Grigg's techniques were associated with lower rates of stomal bleeding, infection, and postoperative complications.⁹ In a randomized trial with a double-blind follow-up comparing the outcomes and the short- and long-term complications of percutaneous translaryngeal tracheostomy (TLT) versus surgical tracheostomy, Antonelli et al. demonstrated lower bleeding rates with TLT, no evidence that TLT increases the risk of bacteremia caused by the spread of upper respiratory tract microbes, and similar long-term effects (physical and emotional) between the two procedures.¹⁰

SURGICAL TRACHEOSTOMY VERSUS PDT

Tracheostomy techniques are evolving and improving. Various PDT devices have been developed to minimize risk and simplify the procedure. Operator experience and the degree of patient complexity can influence the choice of technique in each case. Two basic tracheostomy methods are available: PDT and surgical tracheostomy. The choice of whether to use one or the other in a particular situation depends on available resources, operator experience, and patient factors.

SURGICAL TRACHEOSTOMY

Surgical tracheostomy is usually performed at the bedside in the ICU. Though more difficult because of suboptimal conditions of lighting, suction, sterility, and cautery, bedside tracheostomy avoids the need to transport the patient to the operating room, making it ideal for selected critically ill patients. In addition, it may be performed in the operating room prior to the neck or head surgery. Although PDT has become the procedure of choice in patients undergoing an elective tracheostomy, surgical tracheostomy remains the method of choice in selected critically ill patients with distorted neck anatomy, a history of prior neck surgery, history of cervical irradiation, recent maxillofacial or neck trauma, morbid obesity, a difficult airway, or marked coagulopathy.

The proportion of patients receiving a PDT or surgical tracheostomy varies across different practice settings. A surgical tracheostomy is largely performed in ICUs managed by surgeons, and PDT is preferred in ICUs managed by intensivists, while both techniques are adopted in medical and surgical ICUs.¹¹⁻¹⁶

PDT

Since the technique was first described by Ciaglia (using a guide wire),¹ new methods have been developed by combining the percutaneous nephrostomy multiple-dilator procedure and a variant of vascular access described by Seldinger in 1953. In 1990, Griggs described the guide wire dilator forceps technique (GWDF) (Portex Limited, Hythe, Kent, UK), an improvement on the Rapitrach method in which the forceps was inserted along the guide wire and opened to the size of the skin incision to dilate the trachea¹⁷ (Fig. 38-1). Ciaglia's initial serial multiple dilator technique (MDT) was revised in 1999 for use with a single tapered dilator (SSDT) with a hydrophilic coating. This permits, in a single step, the complete dilatation of pretracheal tissues known as the Blue Rhino technique (Cook Critical Care, Bloomington, IN, USA).¹⁸ In 1997, Fantoni described the translaryngeal method (TLT) (Mallinckrodt, Mirandola, Italy), which does not require the external compression of the tracheal tissues, in which the dilator is passed from the inner to the outer tracheal wall.¹⁹ In 2005, a screw-like device was designed to open the tracheal stoma (rotational dilation technique), which is useful in cases in which the view of the tracheal lumen is lost during bronchoscopy and minimizes the risk of posterior tracheal wall injury (PercTwist method, Rüschi GmbH, Kernen, Germany).²⁰

The Ciaglia Blue Dolphin system (balloon dilatational tracheostomy method) was introduced in 2008. It represents the latest technique derived from the Fogarty balloon embolectomy catheter used in

FIGURE 38-1 ■ Guide wire dilator forceps technique (Portex Limited, Hythe, Kent, UK). The operator shows the surgical forceps.

FIGURE 38-2 ■ Ultrasound in preoperative neck evaluation before performing a PDT or surgical tracheostomy.

vascular surgery. This device primarily generates a radial force to widen the tracheostoma in a single-step dilatation, minimizing bleeding and tracheal ring injury, while achieving good cosmetic results following decannulation.²¹

The success of PDT rests on the expertise of ICU specialists or surgeons in ICU settings (mixed medical and surgical, only medical or surgical). Moreover, the availability of different techniques should enable physicians to optimize the procedure in particularly challenging clinical scenarios, such as obesity, neurotrauma or vascular abnormalities with a high risk of bleeding, ultimately minimizing complications and allowing physicians to choose the method with which they feel most comfortable (Fig. 38-2).

A systematic review and meta-analysis of PDT in critically ill patients recently investigated the advantages of PDT versus surgical tracheostomy in relation to major and minor intraprocedural complications.²² The review included 13 randomized clinical trials (RCTs) published in the past 10 years on tracheostomy in medical, neurologic, or surgical ICU settings. The results demonstrated the equivalence of all techniques regarding the incidence of side effects and the rate of procedure success. The exception was TLT, which was associated with

more severe complications and the more frequent need for a conversion to a different tracheostomy technique.

TIMING OF TRACHEOSTOMY

Older guidelines recommended tracheostomy after 3 weeks of endotracheal intubation only if the extubation did not occur by 21 days.²³ However, defining and predicting the need for prolonged mechanical ventilation continues to pose a major methodologic challenge. With the exception of emergency procedures, the timing for performing a tracheostomy in patients requiring prolonged mechanical ventilation is controversial. However, the real issue behind the debate is how to measure the effectiveness of early tracheostomy and its effects on outcome.

A meta-analysis published in 2005 reported that early tracheostomy shortened the duration of mechanical ventilation and the length of ICU stay.²⁴ In their study involving 1044 patients, Fei Wang et al. suggested that tracheostomy timing did not significantly alter major clinical outcomes in critically ill patients.²⁵ Italian and French RCTs, published by Terragni and Trouillet, respectively, evaluated the benefits and risks of tracheostomy and the ability to identify early patients requiring prolonged mechanical ventilation.^{26,27} Both trials enrolled candidates for tracheostomy. In the first study, respiratory function was improved in a significant number of patients (43.3%) randomized to the late tracheostomy group so that tracheostomy was no longer necessary. Likewise, in the French study, only 27% of patients in the prolonged mechanical ventilation group underwent a late tracheostomy.

The TracMan U.K. randomized trial analyzed survival in early versus late tracheostomy and confirmed the results of the previous trials.²⁸ In the early group, 91.9% of the patients enrolled received a tracheostomy, whereas only 44.9% in the late tracheostomy group underwent a tracheostomy. No significant differences in mortality or other major secondary outcomes between the two groups were found.

Consequently, these results should convince clinicians that routine early tracheostomy does not necessarily reduce the incidence of ventilator-associated pneumonia (VAP), shorten hospital stay, or lower mortality. In general, a tracheostomy should not be performed earlier than 13 to 15 days of OTI.²⁹

Selected patients with neurologic injury can benefit from prolonged intubation because of their limited ability to clear secretions. Prolonged intubation in traumatic brain injury, however, is associated with a high incidence of pneumonia. Conversely, early tracheostomy after trauma reduces the length of ICU stay, days on mechanical ventilation, and incidence of VAP. In patients with infratentorial lesions, Qureshi et al. suggested performing early tracheostomy in patients with acute brain injury because of the low rate of successful extubation in this population.³⁰⁻³³ Although early tracheostomy in selected neurologic patients may reduce the length of ICU stay and pulmonary morbidity, the first 7-10 days after acute brain injury coincide with the highest incidence of intracranial hypertension. Therefore, the appropriate timing of tracheostomy in those patients must be related to the risk of severe intracranial hypertension.³⁴

TRACHEOSTOMY AND SAFETY

Adult tracheostomy can be performed in the operating room or at the bedside in the ICU. To improve PDT safety in different scenarios, suggested procedures to confirm tracheal puncture include a) ultrasound (US) for preoperative evaluation of the neck or during the intraoperative stage for monitoring needle progression through the trachea and b) bronchoscopy surveillance during the procedure, which is increasingly performed by intensivists in critical care. In our experience, PDT is a safe and easy procedure to perform at the bedside even in difficult situations by skilled intensivists with full technical support to minimize complications. For selected patients (e.g., those with distorted neck anatomy or history of prior neck surgery), a surgeon skilled in

the conventional open technique should be readily available even if the team is well trained in PDT.³⁵

BRONCHOSCOPY

Safety during the PDT procedure can be enhanced with bronchoscopy guidance to minimize complications. Several authors have recommended the use of bronchoscopy during PDT because it provides a direct visualization of the airway during tracheostomy tube placement. However, there is no clear consensus in the literature about its use. A recent study comparing the safety and efficacy of PDT procedures with or without bronchoscopy control found no difference in the time of tracheostomy, survival, ventilator-free days, length of ICU stay, or overall hospital stay between the two groups of trauma patients.³⁶ Differences in complications were not statistically significant, but there was a significant conversion rate to surgical tracheostomy among the patients who underwent PDT without bronchoscopy guidance.

Intraoperative endoscopic control has been shown to reduce complications associated with tracheostomy. Bronchoscopy guidance can improve the safety and efficiency by monitoring the placement of the tracheal puncture, the dilational procedure (preventing damage to the posterior tracheal wall and visualizing progression through the interannular membrane without breaking the tracheal rings), insertion of the tracheal cannula, and postprocedure control to detect intratracheal lesions and confirm the correct endotracheal placement³⁷ (Fig. 38-3).

FIGURE 38-3 ■ At the end of a PDT procedure, the cannula position inside the trachea is verified with a bronchoscope.

US AND PDT

In selected cases, however, even with fiber optic endoscopic control, a tracheostomy can result in serious complications due to the puncturing of venous or arterial vessels in patients with aberrant vascular anatomy. Patton et al. reviewed the incidence and sequelae of bleeding events as a complication of PDT.³⁸ They found that variations in venous (inferior thyroid vein) and arterial anatomy (thyroidea ima artery) led to serious bleeding events that required investigation with diagnostic US and/or radiologic examination before proceeding with PDT.

The presence of an abnormal branch of the innominate artery passing in front of the trachea near the area of a tracheostomy procedure can be detected by clinical evaluation (pulsatile swelling at the base of the neck), but an additional US evaluation could be useful to confirm the complexity of the tracheostomy procedure and may warrant switching to a surgical approach in some cases⁴ (Fig. 38-4).

US alone cannot replace bronchoscopy. Nonetheless, it may help to identify potential bleeding complications when evaluating the anterior neck region. In a recent study, Rajajee et al. reported on a US-guided PDT in a group of acute brain injury patients with morbid obesity or needing cervical spine precautions. US-guided PDT was successful in all cases.³⁹

Although US guidance is potentially promising, no RCTs have compared the safety or efficacy of preprocedural and real-time intraoperative US-guided PDT versus the current standard of care. Observational data suggest the use of US before tracheostomy to prevent vascular complications, but prospective RCTs are needed to evaluate its safety and efficacy in comparison with the traditional landmark-guided technique.⁴⁰

TRACHEO TRAINING

PDT has a steep learning curve.⁴¹ Training in PDT is usually performed on medical manikins or animal models owing to ethical and economic concerns.⁴²⁻⁴⁴ The pig model may provide a more realistic approach.⁴⁵ An Italian group tested the efficacy of the porcine model in developing the skills residents require for successful PDT. The model consisted of a larynx and trachea free from perilaryngeal and peritracheal tissues.⁴⁶ The resulting tissue block was then placed on a backing with an overlapping of sponge and plastic wrapping (simulating the skin) before being inserted into the manikin's neck.

ACKNOWLEDGMENTS

The authors wish to thank Elio Rolfo, MD (Internal Medicine), and Daniela Pasero, MD (Cardio-Anesthesia), of S. G. Battista Hospital, Turin, for providing US images.

KEY POINTS

1. Surveys of tracheostomy use show wide heterogeneity in PDTs, timing, operator experience, and settings.
2. PDT continues to gain acceptance as the method of choice though no single technique has been shown to be superior to another.
3. PDT is not without complications as it has a steep learning curve and requires mastery of procedural skills and extensive expertise.
4. PDT has become the procedure of choice in patients undergoing elective tracheostomy. However, surgical tracheostomy remains the method of choice in selected critically ill patients presenting distorted neck anatomy, prior neck surgery, cervical irradiation, maxillofacial or neck trauma, morbid obesity, difficult airways, or marked coagulopathy.
5. The optimal timing of tracheostomy in patients requiring prolonged mechanical ventilation remains controversial. RCTs provide convincing evidence that a routine early tracheotomy may not necessarily improve the outcome but suggest that performing a tracheotomy when weaning fails must be tempered by the knowledge that many patients could improve with more time.

Positive pressure mechanical ventilatory support provides pressure and flow to the airways to effect oxygen (O_2) and carbon dioxide (CO_2) transport between the environment and the pulmonary capillary bed. The overall clinical goal of mechanical ventilation is to maintain appropriate levels of O_2 and CO_2 content in the arterial blood while unloading the ventilatory muscles. An equally important goal is to provide this support without harming the lungs. Positive pressure mechanical ventilation can be applied through either an artificial airway or a tight-fitting mask (noninvasive ventilation, discussed in detail in Chapter 62).

DESIGN FEATURES OF MODERN MECHANICAL VENTILATORS

Most modern ventilators use high-pressure gas sources to drive gas flow.¹ Tidal breaths are generated by this gas flow and can be classified regarding what initiates the breath (trigger variable), what controls gas delivery during the breath (target or limit variable), and what terminates the breath (cycle variable).² In general, breaths can be initiated (triggered) by patient effort (assisted breaths) or by the machine timer (controlled breaths). Target or limit variables are either a set flow or a set inspiratory pressure. With flow targeting, the ventilator adjusts the pressure to maintain a clinician-determined flow pattern. In contrast, for pressure targeting, the ventilator adjusts flow to maintain a clinician-determined inspiratory pressure. Cycle variables are a set volume, flow, or a set inspiratory time. Breathes can also be cycled if the pressure limits are exceeded. Using this approach, breath delivery algorithms from modern mechanical ventilators can be broken into five basic breaths based upon trigger, target, and cycle criteria: (1) volume control (VC); (2) volume assist (VA); (3) pressure control (PC); (4) pressure assist (PA); and (5) pressure support (PS)² (Fig. 39-1).

The availability and delivery logic of the different breath types define the mode of mechanical ventilatory support.² The mode controller is an electronic, pneumatic, or microprocessor-based system designed to provide the proper combination of breaths according to set algorithms and feedback data (conditional variables). The five most common modes are volume assist-control (VACV), pressure assist-control (PACV), volume synchronized intermittent mandatory ventilation (V-SIMV), pressure intermittent mandatory ventilation (P-SIMV), and stand-alone pressure support ventilation (PSV).

Novel ventilator designs incorporate advanced monitoring and feedback functions into these controllers to allow continuous adjustments in mode algorithms as the patient's condition changes.³ The most common of these new feedback designs is the addition of a volume target feedback feature to PACV or PSV, termed the *pressure-regulated volume control* (PRVC) and *volume support* (VS), respectively. This feature adjusts the inspiratory pressure level to achieve the volume target. Feedback mechanisms of pressure-targeted breaths can also incorporate inputs (e.g., end tidal CO_2 , minute ventilation, or respiratory rate) in addition to tidal volume to adjust the inspiratory pressure (e.g., the proprietary "SmartCare" system).⁴

ADVERSE EFFECTS OF POSITIVE PRESSURE MECHANICAL VENTILATION

Ventilator-Induced Lung Injury

The lung can be injured when it is stretched excessively by positive pressure ventilation. The most well-recognized injury is an alveolar rupture, presenting as extraalveolar air in the mediastinum (pneumomediastinum), pericardium (pneumopericardium), subcutaneous tissue (subcutaneous emphysema), pleura (pneumothorax), and vasculature (air emboli).⁵ The risk of extraalveolar air increases as a function of the magnitude and duration of alveolar overdistention. Thus, interactions of the respiratory system mechanics and mechanical ventilation strategies (e.g., high regional tidal volume and PEEP; both applied and intrinsic) that produce regions of excessive alveolar stretch (i.e., transpulmonary distending pressures more than 40 cm H_2O) for prolonged periods, create alveolar units that are at risk for rupture.

Parenchymal lung injury not associated with extraalveolar air and can also be produced by mechanical ventilation strategies that stretch the lungs beyond the normal maximum capacity (i.e., "volutrauma" associated with transpulmonary distending pressures >30 cm H_2O).⁶⁻¹⁰ Pathologically, this manifests as diffuse alveolar damage and is associated with cytokine release¹¹ and bacterial translocation.¹²

In addition to being caused by simple overstretching of the lung, ventilator-induced lung injury (VILI) may have other determinants. Among these may be excessive tidal stretch (i.e., repetitive cycling of the lungs with tidal volumes larger than the normal 4 to 8-mL/kg ideal body weight)¹³ and a shear stress phenomenon that occurs when injured alveoli are repetitively opened and collapsed during the ventilatory cycle.^{9,14-16} Moreover, VILI may be worsened by increasing the frequency of excessive lung tidal stretching and from acceleration forces associated with rapid initial gas flow into the lung.¹⁷

VILI occurs clinically when low-resistance/high-compliance units receive a disproportionately high regional tidal volume in the setting of high alveolar distending pressures (see Fig. 39-2). Concerns regarding overdistention injury is the rationale for using "lung-protective" ventilator strategies that accept less than normal values for pH and O_2 partial pressure in exchange for lower (and safer) distending pressures and volumes.

Cardiac Effects

In addition to affecting ventilation and ventilation distribution, intrathoracic pressure changes resulting from positive-pressure ventilation can affect cardiovascular function.^{18,19} In general, as the mean intrathoracic pressure is increased, the right ventricular filling is decreased. This is the rationale for using volume repletion to maintain cardiac output in the setting of high intrathoracic pressure. In addition, high intrathoracic pressures can increase the right ventricular afterload, further compromising cardiac output. Conversely, elevations in intrathoracic pressure can improve left ventricular function because of an

FIGURE 39-1 ■ Airway pressure, flow, and volume tracings over time depicting the five basic breaths are available on most modern mechanical ventilators. Breaths are classified by their trigger, target or limit, and cycle variables. (Adapted from MacIntyre NR. Mechanical ventilatory support. In: Dantzker D, MacIntyre NR, Bakow E, editors. *Comprehensive Respiratory Care*. Philadelphia: Saunders; 1995.)

FIGURE 39-2 ■ Schematic effects of the ventilation distribution in two-unit lung models with homogeneous mechanical properties, abnormal compliance distribution, and abnormal resistance distribution. Note that in situations involving inhomogeneous lung mechanics, positive-pressure breaths are preferentially distributed to “healthier” regions of the lung and can produce regional overdistention even when a normal-sized global tidal volume is delivered. CL, lung compliance; Raw, airway resistance. (Adapted from MacIntyre NR. Mechanical ventilatory support. In: Dantzker D, MacIntyre NR, Bakow E, editors. *Comprehensive Respiratory Care*. Philadelphia: Saunders; 1995.)

effective reduction in the afterload.¹⁹ Indeed, the sudden release of intrathoracic pressure (e.g., during a ventilator disconnect or spontaneous breathing trial) can sometimes precipitate flash pulmonary edema because of the acute increase in afterload coupled with increased venous return.²⁰

Intrathoracic pressures can also influence the distribution of perfusion. The relationship between alveolar and perfusion pressures in the three-zone lung model can help to explain this.²¹ Specifically, the supine human lung is generally in a zone 3 (vascular distention) state. However, as the intraalveolar pressures rises, the zone 2 and zone 1 regions can appear, creating high \dot{V}/Q units. Indeed, increases in dead space (i.e., zone 1 of the lung) can be a consequence of ventilatory strategies using high ventilatory pressures or in the setting of high PEEP (either intrinsic or applied).

Positive pressure mechanical ventilation can affect other aspects of cardiovascular function. Specifically, dyspnea, anxiety, and discomfort from inadequate ventilatory support can lead to stress-related catechol

release, with subsequent increases in myocardial O_2 demands and risk of dysrhythmias. In addition, coronary blood vessel O_2 delivery can be compromised by inadequate gas exchange from lung injury coupled with low mixed venous O_2 partial pressure due to high O_2 consumption demands by the ventilatory muscles.

Patient-Ventilator Dyssynchrony

Patients can interact with all three phases of an assisted breath: (1) trigger, (2) flow delivery, and (3) cycle.²² Triggering dyssynchronies that manifest as unrecognized or delayed responses to the patient effort can be attributed to insensitive or unresponsive triggering mechanisms or intrinsic PEEP (PEEPi), causing an imposed triggering load on the respiratory muscles.²³ Excessive triggering (“double triggering”) may be derived from circuit motion artifacts, premature breath cycling, or the recently described “reverse” triggering observed during controlled breaths.²² Flow dyssynchrony occurs when the ventilator’s flow delivery algorithm is not matched by the patient effort and is more likely to occur during fixed flow breaths (i.e., flow targeted). Cycle dyssynchrony occurs when the breath cycling criteria are either inappropriately short or long on the duration of effort. Patients dyssynchronous with any of these phases will have unnecessary loads placed on their respiratory muscles, thereby increasing the risk of muscle fatigue. Moreover, dyssynchronous interactions produce discomfort and a sense of dyspnea.

There is no doubt that many dyssynchronies are subtle and of little clinical relevance, and significant dyssynchronies that produce severe patient discomfort are frequently cited indications for the administration of sedatives in many ICUs.^{22,23} Therefore, this may impact the ventilator duration as high sedation usage is linked to longer ventilator use.

Managing dyssynchronies can be a significant clinical challenge. Setting trigger sensitivity to be as sensitive as possible without auto-triggering is crucial. Judiciously, PEEPe in the setting of a triggering load from PEEPi can be helpful. Careful adjustments of flow magnitude, timing, and patterns (especially the use of pressure-targeted, variable-flow breaths) may help optimize flow and cycle synchrony. Finally, the newer interactive modes found for the proportional assist ventilation (PAV) and neurally adjusted ventilatory assist (NAVA) may offer help to optimize synchrony in the future.⁴

Oxygen Toxicity

Oxygen concentrations approaching 100% are known to cause oxidant injury to the airways and lung parenchyma.²⁴ The majority of the data supporting this concept, however, are derived from animal studies, and animals and humans often have different O₂ tolerances. It is unclear what the “safe” O₂ concentration or duration of exposure is in sick humans. Most consensus groups have argued that Fio₂ values less than 0.4 are safe for prolonged periods and that Fio₂ values greater than 0.8 should be avoided if possible.

Ventilator-Related Infections

Mechanically ventilated patients are at an increased risk of pulmonary infections for several reasons:^{25,26} (1) The natural protective mechanism of glottic closure is compromised by an endotracheal tube. This permits the continuous seepage of oropharyngeal material into the airways. (2) The endotracheal tube itself impairs the cough reflex and serves as a potential portal for pathogens to enter the lungs. This is particularly important if the circuit is contaminated. (3) Airway and parenchymal injury from both the underlying disease and management complications make the lung prone to infections. (4) The intensive care unit (ICU) environment itself, with its heavy antibiotic use and the presence of very sick patients in close proximity, poses a risk for a variety of nosocomial infections, often from antibiotic-resistant organisms.

Preventing ventilator-associated tracheobronchitis and pneumonia is critical because the length of stay and mortality are heavily influenced by their development.^{25,26} Handwashing and carefully chosen antibiotic regimens for other infections can have important benefits. Management strategies that avoid breaking the integrity of the circuit (e.g., circuit changes only when visibly contaminated) also appear to be helpful. Finally, the continuous drainage of subglottic secretions may be a simple way of reducing lung contamination with the oropharyngeal material.

APPLYING POSITIVE PRESSURE MECHANICAL VENTILATION

Tradeoffs

To provide adequate support while minimizing VILI, mechanical ventilation goals must involve tradeoffs. Specifically, the need for potentially injurious pressures, volumes, and supplemental O₂ must be weighed against the benefits of gas exchange support. To this end, a revision of the gas exchange goals has occurred over the past decade, including pH goals as low as 7.15 to 7.20, and O₂ partial pressure goals as low as 55 mm Hg, are now considered acceptable if the lung can be protected from VILI.²⁷ Ventilator settings are thus selected to provide at least this level of gas exchange support while simultaneously meeting two mechanical goals: (1) the provision of enough applied or “extrinsic” PEEP (PEEPe) to enlist the recruitable alveoli and (2) the avoidance of a PEEP–tidal volume combination that unnecessarily overdistends the lung regions at end inspiration. These goals embody the concept of a “lung-protective” mechanical ventilatory strategy,²⁸ and these principles guide the current recommendations for the specific management of parenchymal and obstructive lung disease.

Managing Parenchymal Lung Injury

Parenchymal lung injury describes disease processes that involve the air spaces and interstitium of the lung. In general, parenchymal injury produces stiff lungs and reduced lung volumes. In addition, the residual functional capacity is reduced, and the compliance curve is shifted to the right.²⁹ It is important to realize, however, that in all but the most diffuse diseases (e.g., diffuse cardiogenic edema), there are often marked regional differences in the degree of inflammation present and, thus, the degree of mechanical abnormalities that exist.^{29–32} This heterogeneity can have a significant impact on the effects of a particular

mechanical ventilation strategy. This is because delivered gases will preferentially go to the regions with the highest compliance and lowest resistance (i.e., the more normal regions) rather than to sicker regions with low compliance (see Fig. 39-2). A “normal-sized” tidal volume may thus be distributed preferentially to the healthier regions, resulting in a much higher regional tidal volume and the potential for regional overdistention injury.³⁰

Frequency–tidal volume settings for supporting a patient with parenchymal lung injury must focus on limiting end-inspiratory stretching. The importance of this limitation on improving the outcome has been suggested by several clinical trials.^{33,34} However, it was most convincingly demonstrated by the NIH ARDS Network trial that showed a 10% absolute reduction in mortality with a ventilator strategy using a pressure <30 cm H₂O and tidal volumes calculated on an ideal body weight of 6 mL/kg compared with 12 mL/kg.³⁵ As a result, the initial tidal volume settings should begin at a 6-mL/kg ideal body weight. Moreover, strong consideration should be given to further reducing this setting if plateau pressures, adjusted for any effects of excessive chest wall stiffness, exceed 30 cm H₂O. Increases in the tidal volume settings might be considered if there is marked patient discomfort or suboptimal gas exchange, provided that the subsequent plateau pressure does not exceed 30 cm H₂O. Respiratory rate settings are then adjusted to control the pH. Unlike in obstructive diseases (see later), the potential for air trapping in parenchymal lung injury is low if the breathing frequency is less than 35 breaths per minute and may not develop, even at frequencies exceeding 50 breaths per minute.

Although scaling tidal volume to ideal body weight is logical, recent studies have suggested that this may be overly simplistic in situations with extensive heterogeneous injury and little functioning lung (“baby lung”). Under these conditions, even a 6-mL/kg tidal volume may overdistend the remaining functional lung. To address this concern, strategies that scale the tidal volume to a measured functional residual capacity (i.e., targeting “lung strain”)³⁶ or to system compliance (i.e., limiting the tidal volume/compliance as expressed by the “driving pressure” or plateau pressure minus PEEP to <15 cm H₂O)³⁷ have been proposed. These approaches await outcome studies.

The choice of pressure-targeted or volume-targeted breaths often depends more on clinician familiarity with the two modes than on important clinical differences between them. In general, pressure-targeted breaths are preferable when an absolute pressure limit is desired in the circuit or when the patient effort is very active with variable flow demands. In contrast, volume-targeted breaths are preferable when it is critical to maintain a certain level of minute ventilation. The volume feedback features on pressure-targeted breaths may help combine the advantages of variable flow and a tidal volume target.

Setting the inspiratory time and the inspiratory–expiratory (I:E) ratio in parenchymal injury involves several considerations. The normal I:E ratio is roughly 1:2 to 1:4, and such ratios produce the most comfort and are the usual initial ventilator settings. Assessment of the flow graphic should also be performed to ensure that an adequate expiratory time is present to avoid PEEPi and air trapping. I:E prolongation beyond the physiologic range of 1:1 (inverse ratio ventilation or IRV) can be used as an alternative to increasing PEEPe to improve \dot{V}/\dot{Q} matching in severe respiratory failure.³⁸ A variation on IRV is airway pressure release ventilation (also known as *biphasic* or *bilevel ventilation*).³⁹ Airway pressure release ventilation (APRV) incorporates the ability to breathe spontaneously during the long inflation period of a pressure-controlled breath; a feature that may enhance alveolar recruitment and comfort. It must be emphasized, however, that although IRV/APRV strategies have a physiologic appeal, positive outcome studies supporting their use do not exist.³⁹

There are both mechanical and gas exchange approaches to setting the PEEP–Fio₂ combination to support oxygenation. Mechanical approaches often use either a static pressure–volume plot to set the PEEP–tidal volume combination between the upper and lower inflection points⁴⁰ or stepwise increases in PEEPe to determine the PEEPe level that yields the greatest compliance.⁴¹ A simpler mechanical approach that may reduce inflammatory cytokines involves analyzing

the airway pressure waveform during a set tidal volume with a constant flow breath (i.e., the “stress index”).⁴² If the pressure waveform demonstrates a steady increase, this implies that no recruitment-derecruitment or overdistention is occurring during the breath. In contrast, if the pressure waveform is concave upward, it suggests that overdistention is occurring; if the pressure waveform is concave downward, it implies derecruitment occurred during the previous exhalation. With any of these approaches, a recruitment maneuver could be used to recruit the maximal number of recruitable alveoli before setting the PEEP. FiO_2 adjustments are then set as low as clinically acceptable.

Since these mechanical approaches are time-consuming and technically challenging, gas exchange criteria are often used to guide the PEEP and FiO_2 settings. These generally involve algorithms designed to provide adequate values for the arterial partial pressure of O_2 while limiting PAO plateau pressures and minimizing FiO_2 (Table 39-1).⁴³ Note that constructing a PEEP- FiO_2 algorithm is usually an empiric exercise in balancing arterial O_2 saturation with FiO_2 and depends on the clinician’s perception of the relative “toxicities” of high thoracic pressures, high FiO_2 , and low arterial O_2 saturation. It is important to note that recent meta-analyses of three large trials comparing conservative versus aggressive PEEP- FiO_2 tables (mean PEEP of 7–9 cm H_2O versus mean PEEP of 14–16 cm H_2O) suggested a benefit to the more aggressive strategies in patients with more severe lung injury (i.e., $\text{PaO}_2/\text{FiO}_2 < 200$) and a benefit to the more conservative strategies in less severe lung injury.⁴³

Managing Obstructive Airway Disease

Respiratory failure from airflow obstruction is a direct consequence of increases in airway resistance. Airway narrowing and increased resistance leads to two important mechanical changes: (1) the increased pressures required for airflow may overload the ventilatory muscles, producing a “ventilatory pump failure,” with spontaneous minute ventilation inadequate for gas exchange, and (2) the narrowed airways create regions in the lungs that cannot properly empty and return to their normal resting volume, and PEEP_i is produced.⁴⁴ These regions of overinflation create dead space and place the inspiratory muscles at a substantial mechanical disadvantage, which further worsens muscle function. Overinflated regions may also compress healthier regions of the lung, impairing \dot{V}/\dot{Q} matching. Regions of air trapping and PEEP_i also function as a threshold load to trigger mechanical breaths.^{22,45,46}

Several gas exchange abnormalities can accompany worsening airflow obstruction. First, although there may be transient hyperventilation due to dyspnea in patients with asthma, worsening respiratory failure in those with obstructive lung disease is characterized by a falling minute ventilation as the respiratory muscles become fatigued in the face of airflow obstruction.⁴⁷ The result of this clinical situation is termed *hypercapnic respiratory failure*. Second, as noted earlier, regional lung compression and regional hypoventilation produce a \dot{V}/\dot{Q} mismatch that results in progressive hypoxemia. However,

alveolar inflammation and flooding are not characteristic features of respiratory failure due to pure airflow obstruction. Thus, shunts are less of an issue than in parenchymal lung injury. Third, overdistended regions of the lungs, coupled with underlying emphysematous changes in some patients, result in capillary loss and increase the dead space. This wasted ventilation further compromises the ability of the inspiratory muscles to supply adequate ventilation for alveolar gas exchange. Emphysematous regions have also reduced the recoil properties that can worsen air trapping. Finally, hypoxemic pulmonary vasoconstriction, coupled with chronic pulmonary vascular changes in some airway diseases, overloads the right ventricle, further decreasing the blood flow to the lung and making dead space worse.⁴⁷

Setting the frequency–tidal volume pattern in obstructive lung disease involves many considerations that are similar to those in parenchymal lung injury. Specifically, tidal volumes should be sufficiently low (e.g., 6-mL/kg ideal body weight) to ensure that the plateau pressure is <30 cm H_2O . However, in obstructive disease, clinicians should be aware that high *peak* airway pressures, even in the presence of acceptable values for plateau pressure, may transiently subject regions of the lung to overdistention injury due to a pendelluft effect (see Fig. 39-2). Similar to parenchymal lung injury, tidal volume reductions should be considered to meet the plateau pressure goals. Tidal volume increases can be considered for comfort or gas exchange, provided that the plateau pressure values do not exceed 30 cm H_2O . The set rate is used to control the pH. Unlike parenchymal disease, however, the elevated airway resistance and often low recoil pressures of emphysema greatly increase the potential for PEEP_i and air trapping, which limits the range of breath rates available.

The inspiratory–expiratory ratio in obstructive lung disease is set as low as possible to minimize the development of air trapping. For the same reason, approaches using IRV strategies are almost always contraindicated.

Since alveolar recruitment is less of an issue in obstructive lung disease than in parenchymal lung injury, the PEEP- FiO_2 steps in Table 39-1 should likely be shifted to a conservative strategy that emphasizes FiO_2 for oxygenation support. However, a specific role for applying PEEP in an obstructed patient occurs when PEEP_i serves as an inspiratory threshold load on the patient’s attempt to trigger a breath. Under these conditions, judicious application of PEEP_e (up to 75% to 85% of PEEP_i) can “balance” the expiratory pressure throughout the ventilator circuitry to reduce this triggering load and facilitate the triggering process.^{45,46} In general, PEEP_e below the PEEP_i level has little effect on the total PEEP. However, in rare circumstances, small amounts of PEEP_e have been shown to reduce PEEP_i and air trapping, presumably from splinting open collapsing small airways.⁴⁸

Managing Normal Lungs (Neuromuscular Injury and the Perioperative Setting)

The risk of VILI is thought to be lower in a mechanically ventilated patient with normal lungs because the lung mechanics are often near

TABLE 39-1 NIH ARDS Network PEEP- FiO_2 Tables

| CONSERVATIVE PEEP APPROACH | | | | | | | | | | | | | | | | |
|----------------------------|----|----|----|----|----|----|----|----|----|----|----|----|----|-----|-----|-----|
| FiO_2 | 30 | 40 | 40 | 50 | 50 | 60 | 70 | 70 | 70 | 80 | 90 | 90 | 90 | 1.0 | 1.0 | 1.0 |
| PEEP | 5 | 5 | 8 | 8 | 10 | 10 | 10 | 12 | 14 | 14 | 14 | 16 | 18 | 18 | 20 | 24 |
| LIBERAL PEEP APPROACH | | | | | | | | | | | | | | | | |
| FiO_2 | 30 | 30 | 40 | 40 | 50 | 50 | 60 | 60 | 70 | 80 | 80 | 80 | 90 | 1.0 | 1.0 | |
| PEEP | 12 | 14 | 14 | 16 | 16 | 18 | 18 | 20 | 20 | 20 | 22 | 22 | 22 | 22 | 24 | |

Targets: Po_2 55–80, SpO_2 88%–95%. Move up one step if below target, down one step, if above target. FiO_2 , fraction of inspired oxygen; PEEP, positive end-expiratory pressure (cm H_2O). Data from the National Heart, Lung, and Blood Institute, National Institutes of Health.

normal, making regional overdistention less likely. More “generous” tidal volumes (e.g., up to 10 mL/kg IBW) are thus often used to improve comfort, maintain recruitment, and prevent atelectasis. Challenging these generous tidal volume practices, however, are a series of recent trials in the perioperative setting demonstrating that limiting plateau pressures and tidal volumes reduces postoperative respiratory complications.⁴⁹⁻⁵¹

Regardless of the tidal volume settings, maximal distending pressures should be monitored and kept as low as possible while still being compatible with the other goals noted earlier. Certainly, plateau pressure should always be kept well below 30 cm H₂O. Low levels of PEEP are often beneficial in preventing derecruitment (atelectasis) in these patients, who are often supine and incapable of secretion clearance or spontaneous sigh breaths.

Importantly, in the setting of severe CNS injury, concerns regarding the adverse effects of high intrathoracic pressure and high levels of PCO₂ may require adjustments to the basic lung-protective strategy (e.g., lower PEEP settings and higher minute ventilation settings).

Recovering Respiratory Failure: The Ventilator Withdrawal Process

Once the cause of respiratory failure stabilizes and begins to reverse, attention turns to the ventilator withdrawal process. Numerous evidence-based guidelines have focused on the pivotal role of spontaneous breathing trials (SBTs) in determining the need for continued mechanical ventilatory support.^{52,53} In general, once a patient has stabilized, has an adequate gas exchange, has low PEEP/FiO₂ needs, and is off vasopressors, daily SBTs should be initiated. Importantly, SBTs should be linked to a sedation minimization protocol for maximal success.

In patients comfortably tolerating an SBT for up to 2 h, an assessment should be made to determine if the artificial airway can be removed. In patients failing the SBT, comfortable forms of interactive ventilatory support should be provided until the next attempt at an SBT. This is usually the next day but may be more frequent in patients with rapidly recovering lung function (e.g., post anesthesia or drug overdose). Although the pressure-support mode is often used for this purpose, the pressure-assist control can also fill this role. When using pressure-assist control, the control rate is set quite low (or even to zero), and the inspiratory pressure is titrated to achieve comfort. Similar to pressure support, this approach is patient triggered and pressure targeted but is time cycled as opposed to flow cycling for pressure support.

More detailed discussions on the ventilator discontinuation process can be found in Chapter 63.

CONCLUSION

Positive pressure mechanical ventilatory support is a critical component in the management of patients with respiratory failure. However, it is important to note that this technology is supportive, not therapeutic, and it cannot cure lung injury. Indeed, the best we can hope for is to buy time by supporting gas exchange without harming the lungs.

Positive pressure mechanical ventilation is designed to provide substantial levels of respiratory support. The major goals are to unload the ventilatory muscles and optimize ventilation-perfusion matching to ensure adequate gas exchange. Important complications include ventilator-induced lung injury, cardiac compromise, oxygen toxicity, and patient discomfort. Applying ventilatory support often requires tradeoffs as clinicians attempt to balance gas exchange needs with the risk of these complications. Future innovations cannot focus simply on physiologic endpoints. Rather, innovations should demonstrate benefits in clinically relevant factors, such as mortality, ventilator-free days, barotrauma, and costs. Only then can we properly assess the often bewildering array of new approaches to this vital life-support technology.

KEY POINTS

1. Ventilator breath delivery is characterized by the trigger, target, and cycle variables.
2. The interaction of a positive-pressure breath and respiratory system mechanics is summarized by the equation of motion:
Airway pressure = (Flow × Resistance) + (Volume/System Compliance) + PEEP
3. The goal of positive pressure mechanical ventilation is to provide adequate gas exchange while protecting the lung from overdistention and recruitment-derecruitment injury.
4. Positive pressure mechanical ventilation in obstructive lung disease poses the additional risk of producing overdistention from air trapping.

ANNOTATED REFERENCES

An excellent review attempting to link important data from animal studies of ventilator-induced lung injury to the clinical setting, with an emphasis on how ventilator strategies can produce both lung and systemic injury.
- NIH ARDS Network. Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. *N Engl J Med* 2000;342(18):1301–1308.
This landmark study clearly established the link between excessive lung stretching during mechanical ventilation and worse survival in patients with acute lung injury. The message from this paper is very clear: Although large tidal volumes may improve gas exchange, they ultimately cause harm by overstretching healthier regions of the lung.
- Pinsky MR, Guimond JG. The effects of positive end-expiratory pressure on heart-lung interactions. *J Crit Care* 1991;6(1):1–15.
An excellent overview of the complex interactions of intrathoracic positive pressure and cardiac function. The fact that the dual effects of decreased right heart filling and decreased left ventricular afterload can have both positive and negative effects is carefully explained.

This two-part report comprehensively reviews all aspects of respiratory system mechanics as they apply to mechanical ventilation. Both theory and practical applicability are provided.
- Briel M, Meade M, Mercat A, et al. Higher vs. lower positive end-expiratory pressure in patients with acute lung injury and acute respiratory distress syndrome: systematic review and meta-analysis. *JAMA* 2010;303(9):865–873.
This is a meta-analysis of the three large trials conducted in the past decade examining high-versus low-PEEP strategies in the setting of low-V_t ventilation. The results indicate that in ARDS patients, a high-PEEP strategy offers a mortality benefit. However, in the less severe ALI patients, a high-PEEP strategy trended toward a worse mortality.

Acute kidney injury (AKI) is a common complication in critically ill patients admitted to the intensive care unit (ICU).¹⁻³ Recent epidemiologic data suggest that over 50% of ICU patients suffer from AKI and that up to 13.5% will be treated with renal replacement therapy (RRT).¹⁻³ Changes in patient characteristics, with admission of older patients with more comorbidities such as diabetes, cardiovascular disease, and hypertension, have resulted in a marked increase in the proportion of patients treated with RRT in the past decade.^{4,5} RRT has, therefore, become an essential and commonly used treatment option for ICU patients.

■ TECHNICAL ASPECTS OF RRT

RRT is most often delivered via extracorporeal techniques. Alternatively, the peritoneum of the patient can be used as a semipermeable exchange membrane. This latter technique is primarily used in resource-poor areas and seldom in developed countries.

Extracorporeal techniques can be done with different modalities (Table 40-1). These are named according to the duration of RRT and the technique used to exchange solutes and water (either diffusion or convection).

Diffusion and Convection

Exchange of waste products over a semipermeable membrane can occur via diffusion (hemodialysis [HD]) or convection (hemofiltration) (Fig. 40-1).

In diffusion, blood and dialysate flow countercurrent on both sides of the semipermeable membrane of the hemofilter. The driving force that moves solutes across the semipermeable membrane is the solute concentration gradient. Uremic toxins, such as blood urea nitrogen and creatinine, will have high blood concentrations and are absent in the dialysate. Other factors that determine the movement of solutes from the blood to dialysate are the diffusion coefficient of the membrane, its thickness, and its surface area. Diffusion is very efficient in removing small molecules, such as potassium, ammonium, and creatinine (<20 kDa); it is less efficient in removing larger solutes and water.

In hemofiltration, solutes and water are transported over the membrane by a difference in pressure between both sides of the membrane. Pressure forces the water and solutes from the blood compartment to the so-called effluent. The permeability coefficient of the membrane and the difference in pressure between both sides of the membrane determine the amount of fluid and solutes transported across the membrane via convection. The effluent rate is controlled by a pump. Hemofiltration is more efficient for removal of water and larger molecules (<60 kDa). In hemodiafiltration, both convection and diffusion are combined.

There are currently no data to suggest the superiority of diffusion over convection.

Duration of RRT

Intermittent hemodialysis (IHD) is a very efficient dialysis technique, performed during a 3- to 4-h period. Continuous renal replacement therapy (CRRT) is less efficient; it is conducted 24 h per day. Hybrid techniques, alternatively termed *sustained low-efficiency daily dialysis*

(SLEDD) or *extended daily dialysis* (EDD), have intermediate efficacy and are used 6 to 12 h per day.^{6,7}

Intermittent and hybrid therapies are performed with dialysis machines that are also used for chronic dialysis patients. These machines typically have more complicated interfaces and are, therefore, often managed by dialysis nurses. CRRT is most often performed with specially designed machines with a relatively simple interface, which are managed by ICU nurses.

Specific Aspects of a CRRT Circuit

Figure 40-2 illustrates the different aspects of CRRT, performed as continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF).

The dose of CRRT is by convention expressed as the clearance of urea, a small molecule that is not retained by the membrane in either HD or hemofiltration. The effluent rate, which is the volume of fluid produced by hemofiltration and/or HD, therefore equals the clearance of urea and, when corrected for body weight, can be used to express the dose of CRRT: dose of CRRT = effluent rate per hour per kg body weight (mL/kg/h). For a desired dose of 25 mL/kg/h in a 60-kg patient, the effluent rate will be $25 \times 60 = 1500$ mL/h. This effluent needs to be partly or completely replaced by another fluid; otherwise body fluid losses will be too high. The amount of effluent that is replaced will determine the fluid balance of the patient. This replacement fluid can be given prefilter (predilution), postfilter (postdilution), or as a combination of both. When the fluid is given by the postdilution mode, blood will concentrate while passing through the capillaries of the hemofilter. This may lead to clogging (partial clotting) and clotting of the capillaries, leading to decreased efficacy because fewer capillaries are available. To prevent this, a filtration fraction (the ratio of effluent flow over plasma flow) of <25% is advised. The filtration fraction is indicated on the dashboard of present-day CRRT machines. On the other hand, predilution administration will dilute the blood in capillary filters, leading to a decreased risk for clotting but also decreased clearance and efficacy.

Dose of RRT

In CRRT, the delivered dose should be 20 to 25 mL/kg/h of effluent. Two large prospective randomized studies compared this dose to a higher dose and found that outcomes were similar.^{8,9}

In intermittent RRT, the minimum delivered dose of dialysis should be 3 sessions per week lasting at least 4 h, with a blood flow of >200 mL/min and a dialysate flow of >500 mL/min or a Kt/V index of >3.9 per week, or maintenance of the predialysis urea concentration of 20 to 25 mmol/L.^{9,10}

Anticoagulation

Coagulation is one of the major barriers to effective extracorporeal therapies. When blood leaves the body, the coagulation cascade becomes activated, which can lead to thrombocyte activation, partial clogging (which lowers the effectiveness of dialysis), and even complete clotting/blockage of the dialysis/extracorporeal circuit (resulting in

TABLE 40-1 Renal Replacement Therapy Modalities

| MODALITY | ABBREVIATION | TREATMENT DURATION (per day) | BLOOD FLOW (mL/h) | DIALYSATE FLOW (mL/min) |
|--|--------------|---------------------------------|----------------------|----------------------------|
| Intermittent hemodialysis | IHD | 2-4 h | 150-450 | 300-600 |
| Hybrid techniques | | 6-12 h | 100-200 | 250-500 |
| • Slow low-efficiency daily dialysis | SLEDD | | | |
| • Extended Daily Dialysis | EDD | | | |
| • Prolonged Intermittent Renal Replacement Therapy | PIRRT | | | |
| Continuous Renal Replacement Therapy | CRRT | 24 h | 100-250 | 15-60 |
| • Continuous venovenous Hemodialysis | CVVHD | | | |
| • Continuous venovenous Hemofiltration | CVVH | | | |
| • Continuous venovenous Hemodiafiltration | CVVHDF | | | |
| Peritoneal dialysis | PD | 6 × 2-4 h | | |

FIGURE 40-1 ■ Diffusion (as in hemodialysis) and convection (as in hemofiltration). V, venous blood prefilter and postfilter; R, replacement fluid.

loss of extracorporeal blood). Anticoagulation for RRT should be tailored according to the patient's characteristics and the modality chosen. The risk for coagulation rises with low blood flow or when the vascular access is not functioning well. Special attention is required for non-anticoagulant strategies to avoid coagulation of the circuit. Patients with a high hematocrit are at higher risk for clotting of the extracorporeal/dialysis circuit because of the higher viscosity of their blood. The local hematocrit in the filter rises when ultrafiltration is applied. Therefore, the filtration fraction (ratio of ultrafiltrate flow to blood flow) may not exceed 25% in postdilution RRT. In predilution mode, hemoconcentration is reduced by diluting the blood with

replacement fluids before the blood enters the filter. Blood products should be administered separately from RRT as much as possible. Prompt reaction to pump alarms is important to avoid interruption of blood flow. Careful circuit priming is fundamental. Circuits with a lot of blood-air contact due to the use of drip chambers are especially prone to clotting and require extra attention. There is no evidence pointing toward the efficacy of intermittently rinsing the circuit with saline flushes to prevent clotting.¹¹

- No anticoagulation strategy
Several authors described large series of patients treated without any form of anticoagulation during RRT for AKI (in up to 50%-60%).^{8,9} Especially in patients with a preexisting coagulopathy, an acceptable length of treatment can be reached, even without anticoagulant administration.¹² Risking circuit clotting, in the worst case leading to the loss of approximately 200 mL of extracorporeal blood and eventually also the venous access, may be defensible in patients with a high bleeding risk. Neither the effect of clogging on filter performance nor the consumption of coagulation factors in RRT without anticoagulation is well studied.
- Unfractionated heparin
Unfractionated heparin (UFH), the most widely used anticoagulant, has a half-life between 0.5 and 3.0 h in patients receiving dialysis.¹³ It has a rapid onset of action of approximately 3 to 5 min. Heparin acts by potentiating thrombin and inhibiting activated coagulation factor X (FXa). It is mostly administered as a prefilter infusion, by a variety of regimens, including single-dose, repeated-bolus, or constant-infusion methods. A possible administration scheme is to start with a bolus of 500 to 1000 units, followed by 500 to 750 units/h. Other authors suggest adapting the dose to the body weight, starting with a bolus of 10 to 20 units/kg/h, followed by a rate of 10 to 20 units/kg/h. This maintenance infusion would typically be stopped 30 min before the end of treatment. The dose must be altered for patients exhibiting coagulopathy or an increased bleeding risk. UFH can be easily monitored with routine laboratory tests, such as the activated partial thromboplastin time (aPTT) or activated coagulation time (ACT). Since heparin causes systemic anticoagulation, moderate anticoagulation targets are recommended for ICU patients (1.5-2 times prolongation of the aPTT, or baseline ACT plus 40%). If needed, heparin can be reversed with protamine. Heparin failure, resulting in clotting of the circuit, can be due to antithrombin deficiency or heparin neutralization by binding to plasma proteins. During heparin treatment, the thrombocyte count should be monitored, allowing timely detection of heparin-induced thrombocytopenia (HIT). Current guidelines suggest using heparin for intermittent RRT in patients without an increased bleeding risk, and in the presence of contraindications to citrate, which is used in continuous RRT.
- Low-molecular-weight heparins
Several studies have shown that low-molecular-weight heparins (LMWH) are effective and can be safely used for anticoagulation

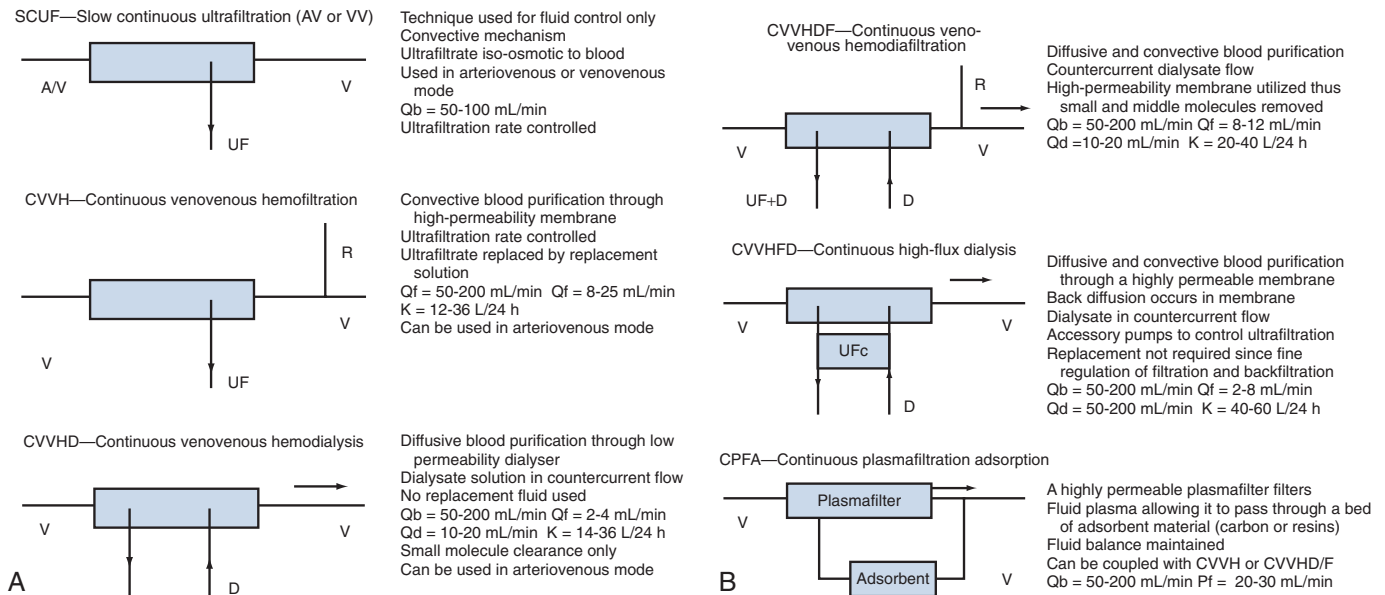

FIGURE 40-2 ■ Schematic representation and definitions of the different continuous renal replacement therapies according to standard nomenclature. Functional capabilities are described. A, artery; D, dialysate; K, clearance; Pf, plasma filtration rate; Q_b , arterial flow; Q_d , dialysate flow; Q_f , ultrafiltration rate; UF, ultrafiltrate; UFc, ultrafiltrate control pump; V, vein.

during chronic HD. LMWH are administered as a single bolus at the beginning of dialysis: immediately after the start of dialysis with postfilter administration or 5 min after the start with prefilter administration.¹⁴ They have a weight-based dosing, require no monitoring when used in short sessions, and have a reduced risk for HIT. The use of LMWH for IHD in AKI is increasing. LMWH are partially cleared during HD (especially with high-flux membranes), but periodic measurement of anti-Factor Xa levels may be useful with prolonged daily use.

- Citrate

The 2012 Kidney Disease Improving Global Outcomes Clinical Practice Guidelines for Acute Kidney Injury have recommended regional citrate anticoagulation as the preferred anticoagulation modality for continuous RRT in critically ill patients for whom it is not contraindicated.¹⁵ Citrate chelates calcium, an essential cofactor for many steps of the coagulation cascade. A whole range of protocols exist, using different dialysate/replacement fluids for the different RRT modalities. Prefilter infusion of citrate, either as a separate trisodium citrate solution or added to calcium-free predilution replacement fluid, lowers ionized calcium levels in the extracorporeal circuit to a level that achieves full blood anticoagulation (i.e., 0.3–0.4 mmol/L). In most protocols, the citrate dose is adapted according to the resulting postfilter circuit ionized calcium measurements, although recently, there has been some concern about the reliability of measurements obtained from point-of-care devices used for this purpose. Citrate and citrate complexes are partially removed in the effluent because of their low molecular weights (198 and 258, respectively) and high sieving coefficients. Citrate clearance is higher with dialysis than with CVVH, with extraction ratios from 20% to 60%, depending on the modality and dose of RRT. Calcium infusion is needed to replace calcium losses and maintain systemic ionized calcium levels within the normal range. The remaining citrate is metabolized in the liver, muscle, and kidney, producing bicarbonate and eventually leading to metabolic alkalosis. Most of the protocols compensate for this by administering a lower concentration of bicarbonate in the replacement fluid. In contrast, in patients with impaired citrate metabolism, acidosis can ensue. Other potential metabolic derangements include hyponatremia (due to metabolism of trisodium citrate),

hypomagnesemia (due to effluent losses in the form of citrate complexes), and hypocalcemia. Citrate accumulation can occur in patients with profound shock or severe liver failure, although recent studies have argued that citrate can be used safely in the latter.¹⁶ During citrate accumulation, there is a simultaneous increase of the total calcium and fall of the ionized calcium. The total calcium to ionized calcium ratio is the best marker for citrate intoxication. When this ratio exceeds 2.5, citrate administration must be stopped. Unintended rapid infusion of a hypertonic citrate solution, causing life-threatening hypocalcemia, is the main risk of citrate anticoagulation. In this situation, it is recommended that the citrate infusion be stopped, while continuing dialysis with a calcium-containing dialysate. In experienced hands, severe hypocalcemia-related complications seldom occur, and regional citrate anticoagulation has been shown to be safe. Treatment protocols should describe how to adjust flows under different conditions to prevent metabolic derangements. Compared with heparin, citrate is associated with lower risk of circuit loss, a lower incidence of filter failure, less bleeding, and lower transfusion rates. Furthermore, citrate is a source of energy and has potential anti-inflammatory effects.

- UFH and protamine

Regional anticoagulation can also be accomplished by the combination of UFH and protamine. Use of this strategy has decreased in parallel with the increasing popularity of citrate. Protamine has several side effects, such as anaphylaxis, hypotension, cardiac depression, leukopenia, and thrombocytopenia. Further, there may be the possibility of a rebound anticoagulant effect because of the shorter half-life of protamine compared with heparin. Regional anticoagulation with heparin-protamine is, therefore, no longer recommended.^{10,15,17}

- Platelet-inhibiting agents

Prostacyclin (PGI_2) and its analogue (nafamostat) inhibit platelet aggregation and adhesion. They have been used alone or in combination with heparin to improve filter survival. There is neither a great amount of data nor a lot of clinical experience with these medications for this purpose, and several guidance documents do not recommend their use in RRT. In addition to these drugs being expensive, there are safety concerns about hemodynamic stability

with the use of PGI₂, and about anaphylaxis, agranulocytosis, and hyperkalemia with the use of nafamostat.

Vascular Access

Vascular access is with a double-lumen catheter, preferably in the right jugular vein or a femoral vein. It is recommended that the subclavian approach not be used for vascular access of a catheter for RRT. Contact of the catheter with the vessel wall may lead to thrombosis and ensuing stenosis, and it may jeopardize the possibility for an arteriovenous fistula in case there is no recovery of kidney function and the patient remains dialysis-dependent. Thrombosis will be more likely to occur when the catheter has a trajectory with angulations, such as when it is inserted into the left jugular vein or subclavian veins.

For optimal blood flow rates, the tip of the catheter should be located in a large vein—that is, the inferior or superior vena cava. Therefore, for an adult, the optimal length of a catheter is 12 to 15 cm for the right jugular vein, 15 to 20 cm for the left jugular vein, and 19 to 24 cm for the femoral veins. There are several different designs of dialysis catheters. At present it is not clear which design is preferable. The outer diameter of catheters varies between 11F and 14F; larger catheter diameters will result in better blood flow rates.

INITIATION OF RRT

At present, the available evidence does not permit the proposal of strict guidelines for the timing of initiating RRT. If exposure to RRT were without risks, we would not wait until the development of absolute criteria. But very early initiation of RRT will expose the patient to potential hazards associated with insertion of the catheter (e.g., blood loss, thrombosis, catheter infection) and exposure to the extracorporeal circuit (e.g., air embolism, hypotension).¹⁸ If RRT offers support in patients with only mild or moderate AKI, early initiation may be beneficial. However, available data suggest no benefit in, for instance, modulation of the inflammatory response,^{19–21} and one study even showed harm when RRT was started very early in patients with severe sepsis or septic shock.²²

Cohort studies on the timing of RRT have shown a benefit from early initiation of RRT.²³ However, the few small prospective, randomized trials that evaluated early initiation of RRT did not show a benefit from early initiation.^{24–26} On the other hand, cohort studies also showed that late initiation is associated with worse outcomes.^{27–29}

Knowledge regarding the deterioration or recovery of kidney function within a certain time period would help us in determining the timing of RRT, especially when there are only relative criteria for initiating RRT (Table 40-2). A clinical risk assessment may identify patients at greater risk for further deterioration of kidney function. This may take into account such risk factors as age, chronic kidney disease, and severity of illness of the patient. Other tools that have been explored are measurements of specific kidney biomarkers and the furosemide stress test.^{30–36}

The kidneys are crucial for the removal of water and homeostasis of electrolytes and acid-base. Volume overload in an anuric patient and severe electrolyte and acid-base abnormalities are, therefore, absolute criteria for the initiation of RRT (Table 40-2).³⁷

CHOICE OF MODALITY OF RRT

Since the introduction of CRRT in the mid-1980s, there has been debate regarding the optimal modality of RRT. Several relatively small studies and meta-analyses showed that CRRT and IHD are associated with similar patient outcomes.^{38,39} However, the number of patients included in individual studies was relatively low, the baseline characteristics of the patients were different, and the techniques used (e.g., modalities, dose, initiation criteria) varied among studies, making comparisons difficult. Renal outcomes may, however, be better when CRRT is used. Cohort studies, as well as a comparison of the large prospective, randomized studies regarding dose, the ATN and RENAL

TABLE 40-2 Criteria for Initiation of RRT

| INDICATION | CHARACTERISTIC |
|--------------------------|---|
| ABSOLUTE CRITERIA | |
| Metabolic abnormality | BUN > 100 mg/dL (35.7 mmol/L) Hyperkalemia > 6 mmol/L with ECG abnormalities Hypermagnesemia > 8 meq/L (4 mmol/L) with anuria and absence of deep tendon reflexes |
| Acidosis | pH < 7.15 Lactic acidosis related to metformin use |
| Fluid overload | Diuretic-resistant |
| RELATIVE CRITERIA | |
| Metabolic abnormality | BUN > 76 mg/dL (27 mmol/L) Hyperkalemia > 6 mmol/L Dysnatremia Hypermagnesemia > 8 meq/L (4 mmol/L) |
| Acidosis | pH > 7.15 |
| Anuria/oliguria | AKI stage 1 AKI stage 2 AKI stage 3 |
| Fluid overload | Diuretic-sensitive |

AKI, acute kidney injury; BUN, blood urea nitrogen; ECG, electrocardiogram.

Modified from Gibney N, Hoste E, Burdmann EA, et al. Timing of initiation and discontinuation of renal replacement therapy in AKI: unanswered key questions. Clin J Am Soc Nephrol. 2008;3:876–880. Tab 1.

studies, suggest that CRRT is associated with better renal recovery and less end-stage kidney disease in survivors.^{8,9,40–42}

CRRT is performed with a lower extracorporeal blood flow and allows removal of fluid over a longer time period and a lower ultrafiltration rate, characteristics that enhance the hemodynamic tolerability of this technique. Hence, CRRT is often recommended for hemodynamically unstable patients,¹⁵ although studies in specialized centers could not demonstrate that CRRT was better tolerated than IHD in shock patients.⁴³

Intermittent techniques, however, use fewer resources since they allow for several treatments with one machine per day, and the dialysate and replacement fluid are produced by the dialysis machines, in contrast to the need to buy these special solutions for CRRT. Whether the cost of CRRT is greater than that of IHD or vice versa will depend on the specific setting.^{44,45} An important argument in favor of IHD and hybrid therapy is that these modalities will allow for mobilization of the patient during the off period. A recent meta-analysis suggests that hybrid therapies are associated with the same outcomes as CRRT, suggesting that increasing the length of intermittent treatment may combine the best of IHD and CRRT.⁴⁶ However, these data were compiled from a limited number of patients in primarily cohort studies, making this conclusion prone to bias.

SPECIAL INDICATIONS

Heparin-Induced Thrombocytopenia

Up to 3% of heparin-exposed patients develop antibodies directed against the complex of heparin and platelet factor 4, resulting in thrombocytopenia with or without thrombosis. If HIT is likely, all heparin administration, including LMWH, heparin-coated dialyzer membranes, and catheter locks containing heparin, must be stopped. Guidance documents recommend various options for anticoagulation during RRT in this circumstance: regional citrate anticoagulation or the use of direct thrombin inhibitors (such as argatroban or bivalirudin) or factor Xa inhibitors (such as danaparoid or fondaparinux).^{10,15,47}

Patients with High Serum Urea Concentration

When using acute RRT in a highly uremic patient (typically >175 mg/dL), precautions should be taken to prevent disequilibrium syndrome.

This rare neurologic condition is characterized by nausea, vomiting, restlessness, and headache. Some patients, however, may progress to seizures, coma, or death. The syndrome is believed to be primarily related to the decreased osmolality of the blood after the initiation of RRT, creating an osmotic gradient between the blood and the brain, which is compensated for by an influx of water into the brain compartment. To avoid brain edema caused by large variations in osmolality, several preventive measures can be taken, targeting a reduction in the plasma urea nitrogen of at most 40%. The dialysis dose can be reduced by lowering blood flow and dialysate flow, using a small dialyzer, and limiting the length of the treatment. The use of a sodium-enriched dialysate may further reduce the risk.⁴⁸

Patients with Intracranial Hypertension or Cerebral Edema

In patients with acute brain injury, AKI requiring RRT may worsen the neurologic status in several ways. The accumulated urea and solutes diffuse from the blood compartment to the brain cells, thereby increasing water uptake by the brain cells. Dysfunction in the blood-brain barrier reinforces this process. The shift of water into brain tissue, as a result of lowered tonicity of plasma with respect to the brain cells (as described in disequilibrium syndrome), may result in increased intracranial pressure causing cerebral hypoperfusion. This is exacerbated by decreased or absent autoregulation of cerebral blood flow due to the brain injury and eventual hypotension during RRT. Both hypotension and disequilibrium can be avoided by the slow progressive removal of fluids and solutes during CRRT, which is in this setting preferred over intermittent RRT. If the patient is also at increased risk for intracranial bleeding, locoregional citrate anticoagulation is recommended.¹⁷

Patients with Hyponatremia

If patients with severe chronic hyponatremia are treated with conventional RRT, the serum sodium concentration can be expected to increase rapidly, exposing patients to the risk of developing osmotic demyelination. High serum urea concentration may protect the brain against this.^{49,50} To avoid osmotic demyelination in patients with chronic hyponatremia, the treatment during a single dialysis session has to be adjusted to provide a rate of correction that does not exceed the generally recommended rate. The easiest way to do this is by choosing a low-efficiency RRT such as CVVH and to maintain the sodium concentration of the replacement fluid slightly higher than the serum sodium concentration. In the routinely available dialysate/replacement solutions, the variability in sodium content is limited. Adapting the sodium concentration can be established by adding sterile water to the replacement fluid bag. Diluting replacement fluid will also result in decreased potassium and bicarbonate concentrations and, therefore, may induce hypokalemia and acidosis. If only HD is available, one can use the lowest available concentration (130 mmol/L), reduce the blood flow rate markedly (to 2 mL/kg/min), and shorten the dialysis time.⁵¹

Prevention of Contrast-Induced Nephropathy

A single dialysis session removes 60% to 90% of contrast media from the blood,^{52,53} and one study argued that periprocedural CRRT may be beneficial in patients with chronic kidney disease.⁵⁴ However, meta-analyses including studies in patients without severe chronic kidney disease could not show a benefit for this strategy.^{52,55} Considering the possible complications, cost, logistical difficulties, and uncertain benefit, several guidelines do not recommend RRT for the prevention of contrast-induced nephropathy.^{15,56}

Patients with Severe Hemodynamic Instability

CVVHD, SLEDD, and continuous HD seem to be equivalent treatment strategies with regard to mortality, kidney recovery, and fluid removal for hemodynamically unstable patients.^{17,46,57–60} Treating those patients requires some precautions: less aggressive ultrafiltration; increasing dialysate sodium and calcium concentrations to 145 mmol/L and 1.5 mmol/L, respectively; adapting the dialysate temperature to obtain isothermal dialysis; connecting afferent and efferent blood lines simultaneously at the start of the procedure; raising the blood flow slowly; and using biocompatible membranes.¹⁷

Patients with Severe Lactate Acidosis

The key issue in the management of lactic acidosis is to treat the underlying cause. Continuous RRT can be performed in critically ill patients with severe lactic acidosis and AKI.⁶¹ Using continuous HD with bicarbonate dialysate, lactate concentrations can be lowered and the pH can be corrected. However, no adequately powered randomized, controlled trial with clinical outcome endpoints has yet evaluated RRT in this setting.⁶²

KEY POINTS

1. Uremia is the accumulation of uremic toxins of different molecular weights associated with pathogenicity secondary to kidney dysfunction.
2. Acute kidney injury (AKI) is a separate syndrome from chronic renal failure and should be approached in a distinct manner.
3. Specific indications exist for the initiation of renal replacement therapy (RRT) in AKI. Early initiation has been shown to be beneficial in cohort studies. The optimal timing of early is at present unclear and may differ in patient groups.
4. Multiple therapeutic modalities of RRT exist to treat AKI. No modality is clearly superior to another. Treatments should be tailored depending on the clinical scenario.
5. Knowledge of prescribed drug pharmacokinetics is important when dosing patients on RRT.

This article reports on the largest randomized prospective trial evaluating the dose of renal replacement therapy in the ICU. This article has set the standard for dialysis dose in the ICU.

RENAL Replacement Therapy Study Investigators, Bellomo R, Cass A, Cole L, et al. Intensity of continuous renal-replacement therapy in critically ill patients. *N Engl J Med* 2009;361:1627–1638.
A landmark randomized clinical trial that shows the absence of beneficial effects of increasing the continuous renal replacement dose from 25 to 40 mL/kg/h.

VA/NIH Acute Renal Failure Trial Network, Palevsky PM, Zhang JH, O'Connor TZ, et al. Intensity of renal support in critically ill patients with acute kidney injury. *N Engl J Med* 2008;359:7–20.
The largest clinical trial on "routine" renal replacement therapy delivery in the United States (using both intermittent and continuous techniques). According to these authors, intensive renal replacement approach does not improve survival.

■ PHYSIOLOGY AND PATHOPHYSIOLOGY

Temperature is a key determinant and a potential modifier of acute hypoxic and posthypoxic injury. This applies during and immediately following a period of ischemia and especially during reperfusion.¹⁻³ Experimental evidence suggests that the role of temperature in modifying ischemic injuries is equivalent to that of perfusion and oxygenation.⁴ The reason for this is that all destructive cascades that can be triggered by ischemia (summarized in Fig. 41-1) are temperature dependent—that is, they are markedly increased by fever and inhibited by mild hypothermia.¹⁻⁴ These processes, sometimes collectively called *reperfusion injury* or *postresuscitation disease*, can continue for hours to several days after the initial injury and can be retriggered by new episodes of ischemia. Most of these processes are temperature-dependent in a more or less dose-dependent fashion; for example, in the temperature range of 30–40°C the metabolic rate, oxygen consumption, and CO₂ production all increase by 7–10% per °C.^{2,5-6} Processes such as neuroinflammation, neuroexcitotoxicity, and apoptosis are all stimulated by fever and inhibited by hypothermia.² Temperature elevations also increase the permeability of the blood-brain barrier and lead to intracellular acidosis and production of toxic metabolites. In addition, seizure tendency can be increased by fever and mitigated by hypothermia.¹⁻²

Even under normal conditions, the average temperature in the (metabolically highly active) brain is slightly higher than core temperature.^{1,2} When fever occurs, brain temperature can rise well above the systemic temperature, especially in patients with acute brain injuries.^{2,7,8} This is due to excess heat generated by some of the ongoing destructive processes (indicated in orange font in Fig. 41-1), which include neuroinflammation, influx of excess calcium into injured brain cells leading to hypermetabolism, free radical production, and heat trapping in injured areas due to local edema formation and vascular blockage (*cerebral thermopooling*).² These processes lead to a general “overheating” of the brain, with additional temperature elevations in injured areas.² Numerous clinical studies have demonstrated that brain temperature exceeds core temperature by 1–2°C in patients with severe brain injury, with temperatures in injured areas exceeding core temperatures by up to 4°C.^{1,2,7,8} The higher brain temperature (especially in injured areas) can cause additional neurologic damage.² This has been conclusively demonstrated in numerous animal experiments, where experimentally induced brain injury increases significantly when animals are externally warmed; this phenomenon is independent of the initial severity of injury and is especially pronounced if hyperthermia coincides with a period of ischemia.^{1,2,9} Conversely, fever control mitigates brain injury in animal models, while inducing hypothermia provides additional neuroprotection.^{2,9}

Fever is a frequently occurring problem in patients with acute neurologic injury; in fact, the vast majority of these patients will develop fever during the course of their intensive care unit (ICU) stay. The most frequent cause is the so-called central fever, which is a direct consequence of the brain injury itself.^{1,2} However, brain-injured patients are also at a very high risk of infections; apart from the risk of complications such as aspiration pneumonia (due to decreased consciousness and diminished protective reflexes), brain injury can

directly induce immune dysfunction (mediated through the vagal nerve, with efferent signals inhibiting proinflammatory cytokine production), leading to an immunocompromised state with increased susceptibility to infections.¹⁰ Therefore, patients with acute brain injury may have central fever, infectious fever, or a combination of both, either simultaneously or sequentially.¹¹ Whatever the cause, the result is that the temperature set point is elevated, triggering the body’s mechanisms to increase core temperature; the patient thus develops fever.

As would be expected when studying pathophysiologic processes, hyperthermia (regardless of its cause) is independently associated with increased risk of adverse outcome in all types of acute neurologic injuries. Clinical studies in acute ischemic stroke (AIS), subarachnoid hemorrhage (SAH), intracranial hemorrhage (ICH), traumatic brain injury (TBI), and cardiac arrest have demonstrated independent correlations among fever and worse neurologic outcomes, higher mortality, and increased length of stay.¹ This has been documented in dozens of observational studies. For example, patients with AIS who develop fever have larger infarct volumes (OR, 3.23) and greater neurologic deficits (OR, 3.06),¹² increased risk of hemorrhagic transformation (OR, 7.3),¹³ and a 3.4- to 6-fold increase in risk of adverse outcomes.¹⁴⁻¹⁵ Fever in patients with cardiac arrest increases the risk of unfavorable outcomes by a factor of 2.3 per °C temperature increase above 37°C.¹⁶ In patients with ICH, the proportion of time spent at temperature higher than 37.5°C within the first 72 hours is independently associated with poor outcomes,¹⁷ and patients with fever have a significantly higher risk of hematoma expansion.¹⁸ In patients with SAH, fever is independently linked to adverse outcomes.^{19,20} Similar findings have been shown in patients with TBI.^{21,22} One study even reported that peak body temperature predicts mortality in patients without cerebral damage.²³

This large detrimental impact is partly explained by the pathophysiology outlined above, with brain temperature far exceeding core temperature and via heat trapping in injured areas.² The generalized increase in metabolic rate with corresponding increases in minute ventilation and oxygen consumption could also be detrimental, depending on the patients’ condition.^{2,24}

However, it should be noted that not all processes triggered by an episode of ischemia are harmful. For example, it has been shown that some degree of neuroinflammation can contribute to cellular repair after an ischemic insult.^{2,25} Furthermore, in some situations, the proinflammatory state that may be associated with fever can help the body fight infections. Fever can inhibit the growth of certain species of bacteria, while simultaneously stimulating immune cell function and enhancing antibody and cytokine synthesis.²⁶ Several studies suggest that suppression of fever with antipyretics in patients with influenza can adversely affect outcomes.²⁷

However, when the processes are uncontrolled and overwhelming, they are harmful and can lead to cell destruction and death. A useful analogy might be the process of infection and inflammation, where an immune response is needed to combat the infection but a cascade of inflammation (as is seen in septic shock) can overwhelm the organism and lead to death. In this situation, mitigating these processes can improve outcomes.

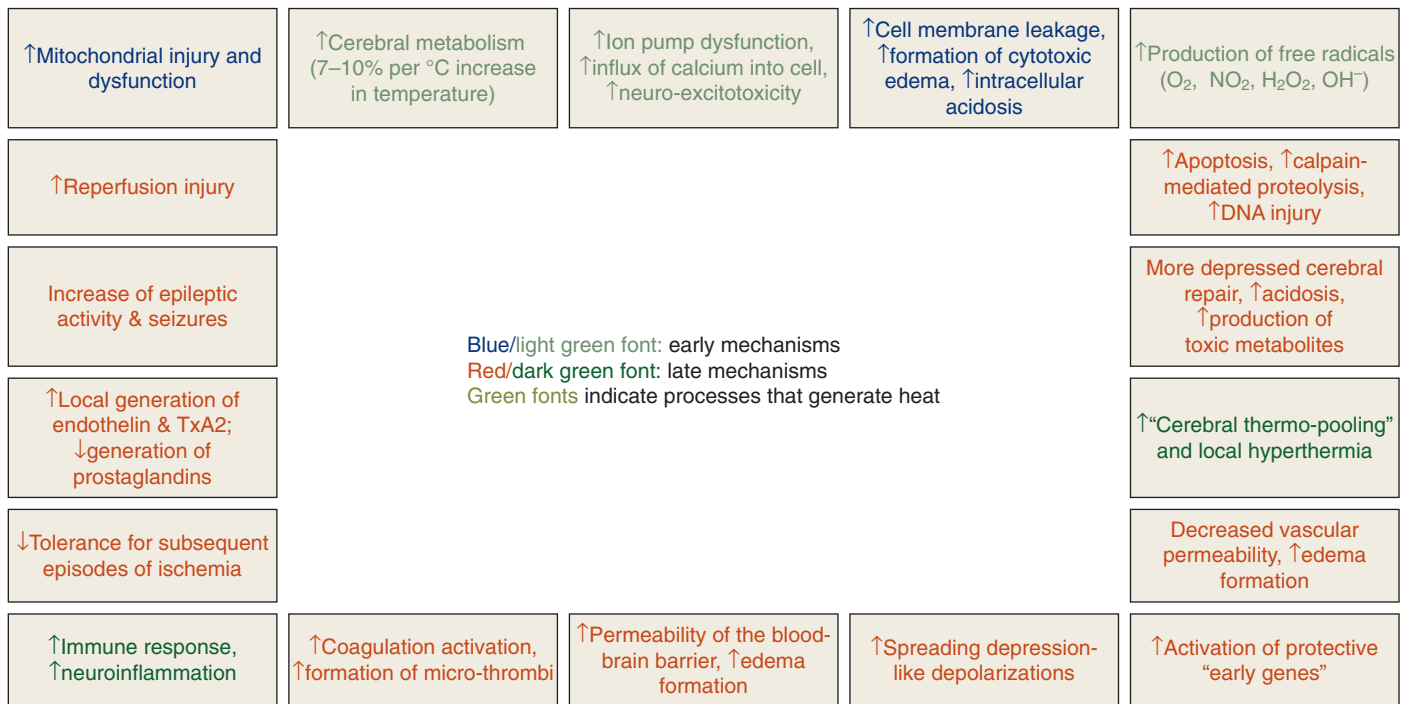

FIGURE 41-1 ■ Mechanisms underlying ischemia-reperfusion injury. (Adapted, with permission, from Polderman KH. Mechanisms of action, physiologic effects, and complications of hypothermia. *Crit Care Med* 2009;37:S186–S202.)

Thus, the potential benefits of fever should be weighed against the risks. This balance may shift even within the same patient, with protective effects of a febrile response outweighing harm in some phases of a disease, while harm outweighs benefits in other phases. The overwhelming majority of patients with acute brain injury is likely to suffer harmful consequences of fever and will benefit from strict fever control or even therapeutic hypothermia (see below).¹¹ As the destructive processes play out over periods of several days and can be restarted by new episodes of ischemia, maintaining an “appropriate” core temperature should be a key goal in care of critically ill patients, especially in those with acute neurologic injuries.^{1,2,11}

As with blood pressure and ventilation, an “optimal” temperature can be determined to suit the individual needs of the patient. Usually, this is normothermia, although in some situations (such as following anoxic brain injury), a below-normal temperature may provide additional benefits; meanwhile, in other situations (such as severe infections in non-brain-injured patients), a mild degree of hyperthermia may be beneficial.

CLINICAL EVIDENCE AND POTENTIAL INDICATIONS FOR TEMPERATURE CONTROL

Though randomized controlled trials (RCTs) assessing benefits of fever control are still lacking, based on the pathophysiologic data discussed above as well as dozens of observational studies showing a link between fever and adverse outcomes, maintaining normothermia is a widely accepted goal in patients with all types of acute brain injuries. Some observational and case-control studies in patients with SAH, AIS, and TBI have reported that aggressive temperature control using a combination of antipyretic drugs and mechanical cooling devices can indeed improve outcomes.^{28,29} Whether hypothermia can further improve outcomes compared to strict fever control remains a matter of debate.

Evidence for use of fever control and/or TH for specific types of injuries is briefly discussed below.

1. Neonatal Asphyxia

Seven multicenter RCTs in babies with perinatal asphyxia have reported significant improvements in neurologic outcomes when treated with TH (32–34°C for periods of 48–72 hours).^{30–36} Benefits in neurocognitive function persist on multiyear follow-up into middle childhood.³⁷ The estimated number needed to treat for the therapy is six. Eight nonrandomized trials have reported similar benefits. Based on these studies, the use of TH in neonatal asphyxia should be considered standard of care.

2. Cardiac Arrest

Two RCTs where patients were cooled to 32–34°C and 44 nonrandomized before-after studies have reported significantly improved outcomes in patients with witnessed cardiac arrest (CA) and an initial rhythm of ventricular fibrillation or ventricular tachycardia.^{38–39} A small RCT comparing cooling protocols of 32.0°C to 34.0°C reported significantly better results with 32°C.⁴⁰ In contrast, a large 2013 RCT found no difference between strict temperature control at 36.0°C compared to that at 33.0°C.⁴¹ The conclusions of this study have been criticized for problems such as prolonged time (10 hours) to target temperature, temperature fluctuations during the maintenance phase, excessively rapid rewarming, potential selection bias limiting generalizability, and other issues.^{42–44} Thus, although there is general agreement on the need for targeted temperature management after witnessed cardiac arrest, the precise target temperature is still being debated. Current guidelines from the American Heart Association (AHA) and Neurocritical Care Society strongly recommend using TH in all patients who have return of spontaneous circulation following witnessed out-of-hospital CA with an initial rhythm of ventricular fibrillation or pulseless

ventricular tachycardia and recommend considering TH for patients with witnessed asystole or pulseless electrical activity arrest.^{45,46} The AHA guidelines recommend strict temperature management with a relatively wide temperature range of 32–36°C, followed by strict fever control.⁴⁵

3. Acute Ischemic Stroke

As outlined above, there is compelling evidence suggesting harmful effects of fever in AIS. Experimental data suggest that mild hypothermia applied in the hours following injury significantly improves neurologic outcomes.^{1–2} Three feasibility studies have used TH in combination with treatments aimed at achieving reperfusion through administration of clot-dissolving drugs and/or mechanical thrombectomy.^{47,48} In these studies, application of TH appeared feasible and safe, though one study reported a high rate of pneumonia in the intervention group (though still with a nonsignificant trend toward better outcomes). Several other nonrandomized trials with a limited number of patients have studied TH as a treatment for brain edema in patients with large middle cerebral artery (MCA) strokes.¹ Outcomes were better compared to historical controls; however, use of TH for this indication has largely been replaced by surgical decompression for malignant MCA infarctions.

The use of TH for a limited period of time in combination with reperfusion appears to be a promising approach, but no large RCTs addressing this issue have been performed to date. Strict fever management after AIS should be the goal of care, with use of TH limited to clinical trials.

4. Traumatic Brain Injury

Experimental data and numerous clinical studies have shown that hypothermia can be used to control intracranial pressure and reduce brain edema in patients with TBI.¹ More than 30 clinical trials enrolling different categories of patients with severe TBI and using periods of cooling ranging from 24 hours to more than a week have shown conflicting results.¹ Several studies using TH in early stages of TBI have reported improved outcomes, while one larger RCT found similar outcomes with strict fever control compared to TH. Several meta-analyses have been conducted, which have suggested benefits when TH was used in early stages and for prolonged periods (>3 days) and when slow rewarming protocols were used.^{1,49} In contrast, a recent large trial using TH to treat refractory ICP rises in later stages of TBI reported significantly worse outcomes in the TH group.⁵⁰ Based on these conflicting results, strict fever control should be the goal in patients with severe TBI, while TH should be used only in the context of clinical trials.

5. Acute Myocardial Infarction

Numerous studies in different animal models (rats, rabbits, sheep, pigs, and dogs) have shown that cooling decreases myocardial injury and reduces infarct size in acute myocardial infarction (AMI).^{1,51–62} Reductions in infarct size ranged from 30% to 90% in these studies, depending on the animal model, area of the heart involved (more cardioprotection in anterior wall infarcts in some experiments), and duration of ischemia.^{51–62} Crucially, hypothermia is only effective when induced before reperfusion; in animal models, the effect is largely lost when cooling is initiated after or even during reperfusion.^{51–62}

Clinical studies attempting to use hypothermia in AMI have been limited by the difficulties in achieving hypothermia before reperfusion. A 2002 RCT randomized 42 patients to PCI with or without hypothermia and reported a nonsignificant infarct size reduction (2% vs. 8% of left ventricular mass).⁶³ Two subsequent RCTs failed to achieve target temperature in the majority of patients enrolled, although both studies found apparent benefits in those patients where core temperatures <35°C were reached before reperfusion (COOL-MI: infarct size 9.3% vs. 18.2%, $P = 0.05$, ICE-IT: 12.9% vs. 22.7%, $P = 0.09$).⁶⁴ However, the number of patients in these subgroups was small, and the subgroups

were not predefined. A subsequent small randomized feasibility trial and a subsequent larger trial (CHILL-MI) used a combination of cold fluid infusion and insertion of an endovascular cooling device to rapidly induce hypothermia. The CHILL-MI trial reported significant reductions in infarct size and lower incidence of heart failure at 45 days in patients with early anterior wall myocardial infarction (MI) who received a PCI within 4 hours⁶⁵; no benefits were seen if treatment was delayed longer, and no effect was noted in patients with inferior wall MI. As achieving low temperatures before reperfusion seems to be required to effect benefits in AMI, newer and more rapid cooling technologies may be required for this indication.⁶⁶

6. Other Potential Indications

Under the right circumstances, hypothermia can improve myocardial contractility (Table 41-1) and has been used in several small studies to treat cardiogenic shock.^{67–73} Several small case series have described the use of hypothermia to treat intracranial hypertension and hepatic encephalopathy in patients with acute liver failure.^{74–77} The appropriate target temperature and duration remain unclear, and in most studies, TH was used as a bridge to transplantation. Some case series and case control studies have reported successful use of hypothermia for adult respiratory distress syndrome,^{78,79} grand mal seizures,^{80,81} SAH,^{82–84} and spinal cord injury.⁸⁴ A larger study assessing TH for severe spinal cord injury is currently ongoing.⁸⁵ The use of TH in all these indications is still experimental, though fever control is regarded as standard of care.

PRACTICAL ASPECTS

Temperature can be increased by *conserving* heat (mainly through vasoconstriction of arteries in the skin) and by *generating* heat (mainly through shivering). Under normal circumstances, vasoconstriction begins at a core temperature of around 36.5°C; the reduction in heat loss resulting from cutaneous vasoconstriction is $\pm 25\%$.⁸⁷ The effectiveness of heat conservation and heat generation decreases with age; this is due to a less effective vascular response (i.e., less vasoconstriction), decreased ability to detect small temperature changes (leading to a slower counterregulatory response), and a lower basal metabolic rate.^{2,87} This means that in general, fever control and induction of hypothermia are easier to achieve and maintain in older patients than in younger ones.

Heat generation through shivering is usually much more active, and, therefore, more effective at temperatures close to the normal range than at temperatures that are several degrees below normal. In patients with a normal hypothalamic set point, the shivering threshold is $\pm 1^\circ\text{C}$ below the vasoconstriction threshold, or $\pm 35.5^\circ\text{C}$. The shivering response peaks at core temperatures around 35°C and decreases significantly at temperatures below 33.5–34°C; in most patients, shivering ceases completely at core temperatures around 31°C, though there is a wide variability among patients. There can be variability within the same patient as well if and when the hypothalamic set point changes (see below).^{2,87,88}

Shivering can be problematic for patient management. Sustained shivering can double the metabolic rate, thereby preventing effective temperature management. In addition, it increases oxygen consumption (by 40%–100%), breathing, and heart rate^{3,87}; furthermore, it induces a stress-like response with tachycardia, hypertension, and elevated intracranial pressure and has been linked to an increased risk of morbid cardiac events and adverse outcomes in the perioperative setting.^{1,3} Therefore, shivering should be aggressively and preemptively controlled, and shivering management should be an integral part of the temperature management strategy. Some common antishivering measures and drug regimens are listed in Table 41-2 and Box 41-1. As explained above, shivering will generally be most active at temperatures around 2°C below the hypothalamic set point (1°C below the skin vasoconstriction threshold).^{2,87} Febrile patients with acute brain injury are likely to have an *elevated* hypothalamic set point, so shivering will occur at significantly higher temperatures.

TABLE 41-1 Effects of Cooling on Key Physiologic Parameters

| | |
|--------------------------------|---|
| Cardiovascular and hemodynamic | <p>Mild hypothermia (32–34°C) decreases heart rate (unless there is a stress-mediated tachycardia, which may occur if the patient is shivering or is otherwise uncomfortable). Of note, the occurrence of hypothermia-induced bradycardia predicts better outcomes in patients following cardiac arrest.⁹²</p> <p>Experimental evidence suggests that mild hypothermia increases membrane stability, thereby decreasing the risk of arrhythmias and improving the likelihood of successful defibrillation. However, more profound (<28°C) hypothermia can increase the risk of arrhythmias, which may be refractory to antiarrhythmic drugs.⁸⁷ Therefore, care should be taken to keep core temperature $\geq 30^\circ\text{C}$. The effect on <i>myocardial contractility</i> is strongly dependent on heart rate. If the heart rate is allowed to decrease along with the temperature, myocardial contractility, as measured by systolic function, usually increases, although there may be a mild degree of diastolic dysfunction. If the heart rate is artificially increased through administration of chronotropic drugs or a pacing wire, myocardial contractility decreases.^{93–96}</p> <p>The hemodynamic effects of TH lead to a decrease in cardiac output (by about 25% when temperature decreases from 37 to 32°C). As metabolic rate will decrease by 35–50%, the balance between supply and demand is improved.</p> <p>Central venous pressure usually rises, and there is also an increase in arterial resistance and a slight rise in blood pressure. This rise in mean arterial pressure is caused by hypothermia-induced vasoconstriction of peripheral arteries and arterioles. This effect is absent or less pronounced in cerebral arteries, where the balance between cerebral blood flow and cerebral metabolism (as measured by oxygen and glucose utilization) is maintained or improved.</p> |
| Electrolytes | <p>Electrolyte disorders may develop especially in the induction phase of cooling, due to a combination of increased renal excretion and intracellular shifts.⁹⁷ Such electrolyte disorders can increase the risk of arrhythmias and have other adverse effects on outcome. Electrolyte levels should be monitored frequently in the induction and rewarming phases (Fig. 2) and maintained in the high-normal range. Potassium levels may rise during the rewarming phase, as potassium that was secreted into the cell in the induction phase is released. This is one of the reasons why rewarming should be done very slowly, giving the kidneys time to excrete the excess potassium. Hyperkalemia will not develop if rewarming is slow and if renal function is not grossly impaired.</p> |
| Other effects on metabolism | <p>Hyperglycemia. TH can decrease insulin sensitivity and reduce insulin secretion by pancreatic islet cells. Thus, patients treated with TH are at higher than average risk of developing hyperglycemia. Conversely, insulin requirements are likely to decrease during rewarming.</p> <p>TH leads to an increase in the synthesis of glycerol, free fatty acids, ketonic acids, and lactate, causing a mild metabolic acidosis in most patients that does not require treatment. In contrast to the pH levels measured extracellularly, <i>intracellular</i> pH levels increase slightly during cooling.</p> |
| Ventilation | <p>The TH-induced decrease in oxygen consumption and CO₂ production should lead to an adjustment in ventilator settings, and blood gases should be monitored frequently, especially during the induction phase. If ventilator settings are not adjusted, this can lead to hypocapnia and cerebral vasoconstriction.</p> <p>A complicating factor is that blood gas values are <i>temperature dependent</i>, and, as most blood gas analyzers warm blood samples to a temperature of 37°C, this should be accounted for prior to analysis; PO₂ and PCO₂ values should also be corrected for temperature. For example, in a patient with a core temperature of 30°C and pCO₂ determined to be 40 mm Hg in an uncorrected measurement, the temperature-corrected pCO₂ value would be 29 mm Hg. In the same patient with an uncorrected PO₂ of 100 mm Hg, the temperature-corrected value would be 73 mm Hg.</p> <p>Further, it is unclear whether target PCO₂ should be kept constant (e.g., at 40 mm Hg) regardless of the actual body temperature (<i>alpha-stat</i>) or corrected for the actual body temperature (so that the “true amount” of CO₂ increases during hypothermia: <i>pH-stat</i>). Which method is better for management of hypothermic patients has not been conclusively settled, but regardless of whether alpha stat or pH stat is used, the effect of temperature on PO₂ should always be taken into account. This also applies to measurements of mixed venous or venous saturation.</p> <p>If it is not possible to obtain blood gas results measured at the patients’ true core temperature, values can be estimated using the following rule of thumb: for pO₂, <u>subtract</u> 5 mm Hg for every 1°C below 37°C; for pCO₂, <u>subtract</u> 2 mm Hg for every 1°C below 37°C; for pH, <u>add</u> 0.012 points for every 1°C below 37°C.</p> |
| Infections | <p>Hypothermia impairs immune function and inhibits inflammatory responses. Indeed, this is one of the mechanisms through which TH can convey protective effects. A recent meta-analysis reported a mild increase in risk of ventilator-acquired pneumonia and bacteremia associated with TH. In patients treated with TH, assessment for infection should include machine workload (i.e., the energy expenditure of the cooling device to maintain target temperature). If energy expenditure increases and the patient is not shivering, this could indicate the presence of infection.</p> <p>Hypothermia also increases the risk of wound infections.</p> <p>Extra care should be taken in cooled patients to prevent bed sores, which are more likely to show progression and/or impaired healing. In addition, extra attention should be paid to catheter insertion sites and to any surgical wounds that may be present.</p> |
| Coagulation | <p>TH induces a mild bleeding diathesis, with increased bleeding time due to effects on platelet count, platelet function, the kinetics of clotting enzymes and plasminogen activator inhibitors, and other steps in the coagulation cascade. Standard coagulation tests will show no abnormalities unless they are performed at the patients’ actual core temperature. The risk of clinically significant bleeding induced by hypothermia in patients who are not already actively bleeding is very low. None of the large clinical trials in patients with TBI, SAH, stroke, or postanoxic coma have reported significantly increased risks of bleeding associated with hypothermia. Nevertheless, patients who are actively bleeding or have a high bleeding risk should not be cooled to temperatures <35°C.</p> |
| Drug clearance | <p>The half-life of many drugs, in particular those metabolized by the liver, can be significantly increased by TH. These include vasopressors (adrenalin and noradrenalin), benzodiazepines, fentanyl, remifentanyl, morphine, propofol, barbiturates, vecuronium, rocuronium, atracurium, phenytoin, nitrates, propranolol, and some volatile anesthetics. In most cases, the effect of hypothermia is to increase drug levels and/or enhance the effect of the drug.</p> <p>It is likely that the metabolism of other drugs with hepatic clearance will be affected by temperature in a similar way, based on their excretion mechanism. These mechanisms should be taken into account when treating patients under hypothermic conditions. Sedation and analgesia should be a specific focus of attention, especially considering that benzodiazepines and opiates can accumulate during hypothermia, complicating neurologic assessment after treatment.</p> |

TABLE 41-2 Medications (Sedating and Nonsedating) That Can Be Used to Control Shivering

| MEDICATIONS TO COMBAT SHIVERING | |
|--|--|
| NONSEDATING | SEDATING |
| Magnesium (MgSO ₄ , MgCl ₂) | Meperidine/pethidine |
| Buspirone | Opiates |
| Ondansetron | Quick-acting: fentanyl, remi-fentanyl; |
| Nefopam | Slow-acting: tramadol, morphine |
| Clonidine | Propofol |
| Ketanserin | Benzodiazepines (midazolam, temazepam, diazepam, etc.) |
| Urapidil | Dexmedetomidine |
| Phystostigmine | |
| Doxapram | |
| Paralytic agents | |

BOX 41-1 Examples of Antishivering Measures and Drug Regimens

POTENTIAL ANTISHIVERING MEASURES

Skin counterwarming is highly effective in most patients and can significantly reduce the dose of antishivering drugs (including sedation) required to manage shivering. This is particularly important when using TH in nonmechanically ventilated patients, such as when treating patients with AMI or AIS.

SOME COMMONLY USED ANTISHIVERING DRUG REGIMENS

Magnesium (bolus 4-8 g over 10-30 minutes, magnesium drip 0.5-1 g/hour; target serum levels up to 2-2.5 mmol/L (4.8-6 mg/dL); extra bolus if shivering is observed if serum level is not yet at target/maximum)

Buspirone 15-60 mg by mouth

Ondansetron 8-mg bolus (once)

Meperidine bolus 12.5-50 mg; some studies have used meperidine drips of 0.5-1.0 mg/kg

Fentanyl bolus 12.5-50 µg, drip 50-200 µg/hour

Dexmedetomidine 0.5-1 µg/kg loading dose, 0.2-1.0 µg/kg/hour maintenance dose

Addition of **acetaminophen** (paracetamol) and/or (in selected patients) **NSAIDs** can help reduce temperature (by between 0.3 and 0.7°C).

The most important physiologic changes associated with induction of hypothermia and some management strategies are listed in [Box 41-2](#). Temperature elevations have the opposite effects.

Another important parameter affecting ease and speed of cooling is body mass: obese patients are more difficult to cool, especially with surface cooling, due to the insulating properties of adipose tissue and because of the greater mass that requires cooling.

Finally, an issue that often confounds studies dealing with the efficacy of temperature management is that severe brain injury can significantly diminish or even obviate the thermoregulatory response; it is, therefore, much easier to cool patients with very severe brain injury (and absent shivering response) than those with less severe injury. Thus “easy” temperature control is, paradoxically, often a poor prognostic sign, whereas increased workload of cooling devices predicts better neurologic outcomes.^{2,87-88}

COOLING METHODS

Cooling technologies can be broadly divided into invasive (core cooling) and noninvasive (surface cooling) methods. [Figure 41-2](#) depicts “optimal” temperature control for a target of 32.0°C (see [Fig. 41-2, A](#)) and a target of 36.0°C (see [Fig. 41-2, B](#)), respectively.

BOX 41-2 Most Frequently Occurring Hypothermia-Induced Changes in Laboratory Measurements

Increase in serum amylase levels
Mild to moderate thrombocytopenia (platelet count 30-100 × 10¹²)
Increase in serum lactate levels (2.5-5 mmol/L)
Hyperglycemia (risk of hypoglycemia during rewarming when insulin requirements decrease)
Electrolyte disorders (low Mg, K, P, Ca)
Increase in liver enzymes (SGOT and SGPT)
Mild metabolic acidosis
Mild coagulopathy
Changes in blood gasses

The theoretical advantages of invasive cooling over surface cooling are as follows:

1. Some studies suggest greater speed of hypothermia/normothermia induction when core cooling is used; however, it is unclear whether more rapid induction improves outcome.
2. Invasive cooling has potentially fewer and smaller temperature fluctuations in the maintenance phase (see [Figs. 41-2, A and B](#)).
3. Some types of endovascular catheters allow continuous central blood temperature measurement.
4. There is no risk of surface cooling-induced skin lesions.
5. The patient is easily accessible—that is, there is no need to cover large areas of the skin to achieve cooling.
6. Less medication may be needed to control shivering because there is more effective shivering suppression with skin counterwarming (i.e., the entire surface area can be warmed using warm air, leading to a significantly diminished shivering response).^{2,6,87,88} In a related issue, there may be better tolerance and less shivering with endovascular cooling when TH is used in awake, nonintubated patients (e.g., for treatment of AIS or AMI to reduce infarct size).

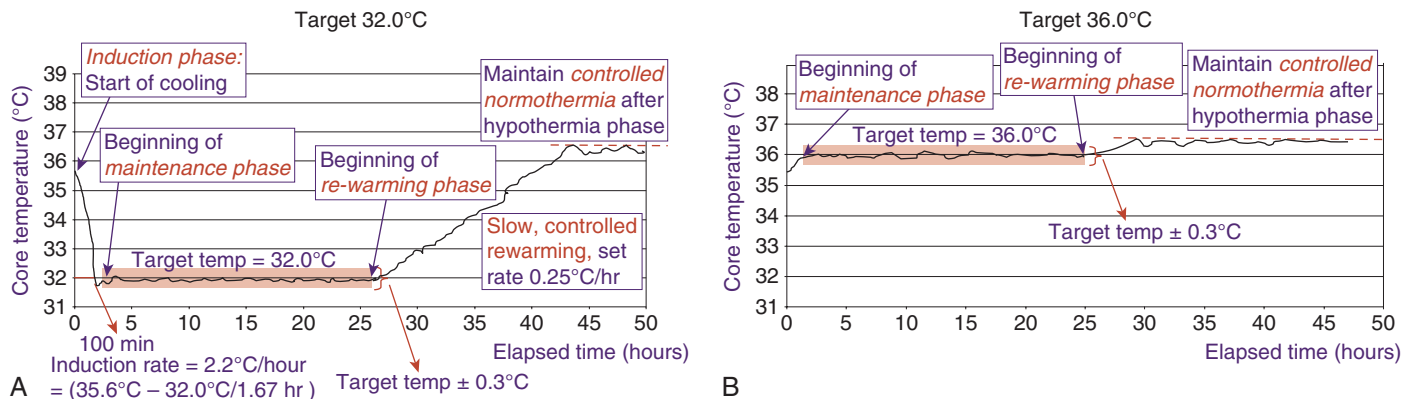

The theoretical advantages of surface cooling over invasive cooling are:

1. Ease of use; can be applied by nurses or nurse practitioners without intervention by a physician
2. No invasive procedure required
3. No delay in initiation of cooling, can be started immediately
4. (Compared to endovascular cooling) no risk of catheter-induced thrombus formation
5. Can be more easily applied outside the ICU setting
6. Combines better with infusion of refrigerated fluids (as this allows simultaneous cooling of both the core compartment and peripheral compartment of the body)

The available data on safety and efficacy of different cooling technologies are limited.^{87,88} Most published studies are small and have evaluated only a single cooling device or method; furthermore, comparative studies have often been retrospective or nonrandomized and/or have enrolled only small numbers of patients. Two large retrospective studies and one RCT suggested that invasive cooling has more rapid and effective temperature control and may help reduce nursing workload⁸⁹⁻⁹¹; in addition, these studies all reported nonsignificant trends toward more favorable outcomes with more accurate temperature control.

In summary, temperature is a key physiologic parameter in critically ill patients. It should be regarded in the same way (and controlling it granted the same importance) as blood pressure, heart rate, and ventilation parameters. As with these other parameters, normothermic values are desired, particularly if the patient has acute brain injury. As a general rule, fever should be avoided, which is easier said than done as the vast majority of these patients will develop fever as both a direct and indirect consequence of the neurologic injury. The availability of improved mechanical cooling devices has allowed improved and more accurate temperature control, and preliminary data suggest that this can lead to further improvements in outcomes.

Different stages of temperature management

The most common anti-shivering measures

- Skin counter-warming using forced air warming blankets.*
- Non-sedating drugs: magnesium (bolus 2–4 grams over 10–20 minutes if shivering occurs; drip with target serum levels up to 4–5 meq/dL; bolus of 2–4 grams IV in 5–20 minutes if shivering occurs); buspirone 15–30 mg;[†] clonidine 0.25–2 mcg/kg/hr.^{‡,§}
- Additional options WITH sedating effect: meperidine 25–100 mg bolus;[‡] opiates (preferably fentanyl bolus dose 25–100 mcg, drip 50–200 mcg/hr, or remi-fentanyl bolus 1 mcg/kg, drip 0.05–0.2 mcg/kg/min);^{‡,¶} dexmedetomidine bolus 0.5–1 mcg/kg in 10 min, drip 0.2–0.6 mcg/kg/hr;^{‡,¶} propofol drip 10–50 mcg/kg;^{‡,¶} benzodiazepines (midazolam, temazepam, or diazepam bolus and/or drips).^{‡,¶}

FIGURE 41-2 ■ “Optimal” temperature control. **A**, Temperature management with set target of 32°C. For the *induction phase* the aim is to get temperature below 34°C and down to the target temperature as quickly as possible. A small overshoot ($\leq 1^\circ\text{C}$) should be regarded as acceptable provided temperature remains $>30^\circ\text{C}$. For the *maintenance phase*, the target is tight control of core temperature, with minimal fluctuations (ideally never more than 0.3°C). The *rewarming phase* should be slow and controlled (warming rate 0.2–0.25°C/hour.). **B**, Temperature management with set target of 36°C. For the *induction phase*, the aim is to get temperature to 36.0°C as quickly as possible. For the *maintenance phase*, the target is tight control of core temperature, with minimal fluctuations (ideally never more than 0.2–0.3°C). More shivering is likely because the target temperature is closer to normal, leading to an enhanced shivering response. There is a greater risk of slipping into supra-normal (febrile) temperature range, especially because brain temperature exceeds core temperature by 1.0–2.0°C at this temperature. *Basic measure, should be used in all patients treated with TTM; if surface cooling used the noncooled areas should be warmed, especially face, hands, and feet. The (theoretical) warming effect on systemic temperature is negligible. Note: The efficacy decreases at higher core temperatures with lower core-skin gradients. [†]PO; [‡]IV; [§]Not available for IV use in the United States; [¶]Use generally limited to intubated patients. (Adapted, with permission, from Polderman KH. How to stay cool in the intensive care unit? Endovascular versus surface cooling. *Circulation* 2015;132:152–157.)

Extracorporeal membrane oxygenation (ECMO), also frequently referred to as extracorporeal life support (ECLS), was first used in clinical settings for respiratory failure in 1972.¹ However, interest has grown substantially in the past 10-15 years, especially in the adult population (Fig. 42-1).

■ TECHNICAL ASPECTS

ECMO can be divided in venoarterial and venovenous modalities (Fig. 42-2).

Venoarterial ECMO

In the venoarterial mode, ECMO removes deoxygenated blood from the central venous system and returns pressurized, oxygenated blood to the systemic arteries. Access can be established directly in the right atrium and aorta via median sternotomy (central) or peripheral vessels (Fig. 42-2, C). Venous cannulation can be performed via the right internal jugular or femoral vein.

Access via the femoral artery is preferred in adults while infants often require carotid artery cannulation. The monitoring of distal blood flow in femoral vessel cannulation should be performed to prevent ischemia or compartment syndrome from venous engorgement. In femoral artery cannulation, a distal perfusion cannula can be placed retrograde and connected via a sidearm to the arterial tubing to provide distal perfusion (Fig. 42-2, A).^{2,3} An alternative approach to femoral cannulation involves sewing a 6- or 8-mm Dacron graft in an end-to-side fashion to the femoral artery to preserve distal flow into the leg.⁴ As flow from the femoral arterial cannulation is retrograde up the aorta, the native cardiac output will often supply the upper body. During severe respiratory failure, hypoxic perfusion to the upper body may result in a “blue upper body, red lower body” syndrome. If cerebral or cardiac oxygenation is deemed to be inadequate, a cannula can be placed into the venous system (usually the right internal jugular vein) and Y’ed into the arterial return from the ECMO circuit. Some portion of oxygenated blood can be directed into the right heart in this hybrid mode and improve oxygenation of the upper body. Similarly, a side graft of dacron⁵ can be used for the axillary arteries (Fig. 42-2, B). However, the upper extremities are more susceptible to hyperperfusion and the development of disabling compartment syndrome.⁶

Venovenous ECMO

In venovenous support, blood is both withdrawn and reinfused into the venous circulation. Thus, adequate cardiac function is required to deliver blood to the systemic circulation. Recirculation of oxygenated blood withdrawn back into the ECMO circuit prior to systemic delivery can severely impact the efficiency of the system. Recirculation can be limited by the return of oxygenated blood in a more proximal location when compared to the drainage (Fig. 42-2, E).

While the femoral veins have been typically utilized, cannulation of the neck vessels, including the internal jugular and the subclavian veins, can provide the patient with greater mobility and prove beneficial in rehabilitation.

A newer generation of cannulas includes the dual-lumen Avalon catheter (Maquet Corp.), which can drain blood from the inferior and superior venae cavae, as well as reinfuse oxygenated blood directly at the tricuspid valve orifice, reducing recirculation. The positioning of this cannula requires fluoroscopy or transesophageal echocardiography and added technical expertise in the manipulation and securing of the cannula^{7,8} (Fig. 42-2, D).

Physical Systems for ECMO

The ECMO system includes cannulas for inflow and outflow, a pump, an oxygenator, and a variety of diagnostic ports and monitors.

Pumps used for ECMO are of the centrifugal or roller types. While each has certain advantages, centrifugal pumps are now most common in adults and used in over 50% of pediatric patients. These pumps are easy to set up and initiate and are much more compact than roller systems. Potential advantages include ease of transport, decreased blood product destruction, and durability. Hemolysis and bleeding complications are lower in some reports and higher in others.

The new-generation membrane lungs made of polymethylpentene are low resistance, easy to prime, have excellent gas exchange, and are reliable often for weeks at a time. The oxygenators used for ECMO should be compact, have low priming volumes, and be reliable over prolonged periods of use.

MANAGEMENT OF ANTICOAGULATION AND BLOOD TRANSFUSION

Despite significant progress in ECLS technology over past decade, thrombosis, embolism, and bleeding remain leading causes of morbidity for patients on ECLS support.⁹⁻¹¹ Exposure of blood to nonbiologic surfaces activates both coagulation factors and platelets, resulting in a prothrombotic state. Intravenous unfractionated heparin (UFH) is the most frequently used anticoagulant that potentiates the activity of intrinsic antithrombin (AT). Moreover, the most commonly used assay to titrate the efficacy of UFH is activated clotting time (ACT). The typical goal of ACT for a patient on ECLS is in the range of 180-220 seconds.¹² Activated partial thromboplastin time (aPTT) assesses the intrinsic and common coagulation pathways. The goal of aPTT is usually between 50 and 70 seconds. In addition, anti-Xa monitoring for the heparin effect is replacing ACT in many centers, with goal levels of 0.3-0.7 IU/mL. No anticoagulation regimen has been shown to be more effective than another in preventing bleeding or clotting.

Patients with suspected heparin-induced thrombocytopenia (HIT) should be switched from heparin to a direct thrombin inhibitor (DTI) (e.g., bivalirudin or argatroban). Therapy with DTIs is typically guided by aPTT in the range 50-70 seconds.^{13,14}

While controversy regarding the goal hemoglobin or platelet count exists, the values commonly applied are provided below¹⁵:

| | |
|--------------------------------------|----------|
| • Platelets (cells/mm ³) | >40-50K |
| • INR | <1.6-1.7 |
| • Fibrinogen (mg/dL) | >100 |
| • Hemoglobin (g/dL) | >7-8 |

FIGURE 42-1 ■ Cardiac (green) and respiratory (blue) extracorporeal life support in adults (greater or equal to 16 years of age), by year in therapy. (Adapted from the Extracorporeal Life Support Organization, www.elso.org.)

ECMO IN RESPIRATORY FAILURE

The primary indication for application of venovenous ECMO is the presence of respiratory failure in the absence of cardiac dysfunction. Venous blood is removed from circulation and, after gas exchange, returns into the venous circulation already enriched with oxygen before entering pulmonary circulation.

ECMO in Acute Respiratory Distress Syndrome (ARDS)

Both the encouraging survival rates of adult ECMO during the H1N1 influenza epidemic and the CESAR trial (which noted increased survival at 6 months in patients receiving care and/or ECMO at an experienced center) have sparked interest for the use of ECMO in severe adult ARDS. Another randomized trial of early ECMO versus conventional therapy for severe ARDS is ongoing (EOLIA trial, NCT01470703) in response to criticism of the CESAR trial.^{9,16-20}

Typical triggers for ECMO initiation include severe hypoxemia, severe hypercapnia with uncompensated acidemia, and excessive airway pressures (Box 42-1). Ideal candidates for ECMO are young patients with severe ARDS and no other organ dysfunction. However, several recent reports of successful ECMO have been published in patients with a variety of comorbidities, multiorgan failure, sepsis, trauma, and hemorrhage.

The recent development of the RESP score, PRESERVE score, and others may prove to be beneficial in identifying optimal patients for ECMO and provide prognostic information.²¹ An online RESP score calculator can be found at <http://www.respscore.com/>.

Once a patient in severe ARDS is placed on ECMO, further management is directed at minimizing ventilator-induced lung injury (VILI) and providing “lung rest.” This approach typically includes pressure-controlled ventilation, limiting the peak inspiratory pressure under 20-25 cm H₂O, a high PEEP of 10-15 cm H₂O, respiratory rate of 6-10/min, and lowest FiO₂ possible.^{22,23} Patients will often have very low tidal volumes (2-4 cc/kg) due to poor compliance in injured lungs.²² Some experts suggest that the application of ECMO to the patients with severe ARDS should be instituted as early as possible to minimize VILI early in the course of the disease.²²

The use of spontaneous breathing modes, to the extent of extubation or early tracheostomy, is currently a trend, especially in adult patients. Minimization of sedation, avoidance of mechanical ventilation, and maintenance of physical activity allow early mobilization and

BOX 42-1

Indications for ECMO in Cases of Severe ARDS²²

Severe hypoxemia—P/F ratio < 50-80
 Severe hypercapnia associated with acidemia (pH < 7.15)
 Excessive end-inspiratory plateau pressure (>35-45 cm H₂O) in the presence of deep sedation and use of NMBS
 Failed proning maneuver
 Potentially reversible cause of respiratory failure
 Absence of conditions associated with poor prognosis

avoidance of deconditioning, which may hasten the recovery post ECMO and improve the long-term quality of life.

ECMO Use in Lung Transplantation

Over the past 5 years, several centers have reported the feasibility of ECMO in patients awaiting lung transplantation with favorable outcomes.²⁴⁻²⁶ An alternative to conventional VV-ECMO is the recently introduced arteriovenous pumpless lung support (iLA; NovaLung) that has been successfully used for hypercapnic respiratory failure and as a parallel low-resistance oxygenator in patients with severe PHTN and RV failure.²⁷

In the posttransplant period, ECMO has been successfully used to support patients with primary graft dysfunction (PGD).²⁸ Although ECMO substantially improves the survival of patients with PGD, allograft function remains considerably impaired in this cohort.²⁹

ECMO Use in COPD

Recently, ECMO and extracorporeal CO₂ removal (ECCO₂R) have been used in patients with chronic respiratory failure due to COPD exacerbation. ECCO₂R systems that utilize small single- or double-lumen catheters with low-flow pumpless or pump-driven circuits have been successfully used for the removal of 25%-50% of CO₂ that leads to a reduction of minute ventilation and the work of breathing.³⁰ In several small series, implementation of ECCO₂R has improved respiratory acidosis, prevented intubation, sped up liberation from mechanical ventilation, improved rehabilitation, and potentially decreased in-hospital mortality and length of stay.³⁰⁻³²

FIGURE 42-2 ■ Schematic of possible venoarterial (A-C) and venovenous (D,E) ECMO circuit configuration. (A) VA, peripheral, femorofemoral. (B) VA, peripheral, femoro-axillary cannulation. (C) VA, central cannulation. (D) VV, single, double-lumen cannula. (E) VV, two single lumen cannulas. ECMO, extracorporeal life support; VA, venoarterial; VV, venovenous. (Adapted from Sangalli F, Patroniti N, Pesenti A. ECMO—extracorporeal life support in adults. Springer, New York: 2014; Figs. 3-9 and 6-6.)⁶⁶

■ ECLS IN HEART FAILURE

Venoarterial extracorporeal support can be used to support the cardiovascular system in cases of cardiac or cardiopulmonary failure as described below.

Postcardiotomy Cardiogenic Shock (PCCS)

With the advent of new strategies for myocardial protection, rates of cardiogenic shock and the inability to wean from bypass have decreased to less than 10%.³³ If patients are unable to be weaned from cardiopulmonary bypass, existing cannulas for bypass can be connected to the ECMO circuit for central cannulation, while peripheral cannulation and chest closure may provide better hemostasis. As venoarterial ECMO increases the afterload of the left heart, rapid failure of the left ventricle can lead to left atrial distention, pulmonary edema, and hemorrhage. Decompression of the left heart can be facilitated with trans-

septal cannulation, and balloon septostomy to create an ASD, or direct LA venting.^{34,35}

The use of ECMO for PCCS is associated with a 25%-33% long-term survival rate, while up to 60% of patients are successfully weaned from ECMO.^{36,37} The majority of survivors recover adequate ventricular function to be weaned from ECMO within 72 hours. Conversion to a long-term assist device or consideration for heart transplant should be discussed if no recovery is obtained within the first 7 days of ECMO. Predictors of increased mortality include age > 70 years, high lactate levels, type A aortic dissection, double valve surgery, as well as presence of acute renal and liver failure.^{33,38}

Acute Myocardial Infarction (AMI)

Cardiogenic shock (CS) accompanies about 5%-7% of AMI. The use of ECLS in the presence of CS allows for the rapid stabilization of the myocardial oxygen supply-demand balance while maintaining

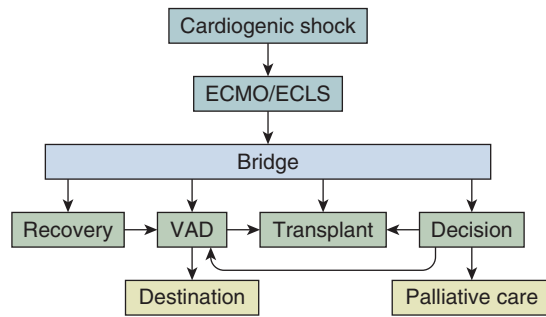

FIGURE 42-3 ■ Decision flow chart of ECLS use in cardiogenic shock/heart failure. VAD, ventricular assist device.

perfusion of the end organs. Once the patient is stabilized, every attempt for coronary revascularization should be made.³⁹ ECLS has been associated with a long-term survival rate between 28% and 35% in this group of patients. However, up to 60% of ECLS served as bridge to VAD or transplants.^{9,40}

End-Stage Heart Failure

Patients in NYHA class IV or INTERMACS class 2 heart failure who are inotrope-dependent or have acute decompensation may require cardiac support as a bridge to transplantation or the placement of a ventricular assist device. ECMO can provide adequate perfusion and reverse organ dysfunction serving as a “bridge to decision” when the suitability of the patient for long-term mechanical circulatory support (MCS) is unclear. Multiple reports suggest good results of ECMO serving as a bridge to transplantation or VAD implantation in patients with end-stage heart failure with a long-term survival rate of 36%-39%^{41,42} (Fig. 42-3).

Myocarditis

Patients with viral myocarditis typically present with new onset of severe single organ failure (cardiac) and have a very good prognosis for recovery. Venoarterial ECMO is used for circulatory support in such patients as recovery often occurs within days to weeks. Overall, the reported survival of patients with fulminant myocarditis supported with ECLS is between 63% and 70%, with 4%-10% of patients bridged to heart transplantation.^{43,44}

Extracorporeal Cardiopulmonary Resuscitation (ECPR)

Over 4800 patients in the ELSO registry have received ECMO during active cardiopulmonary resuscitation (ECPR), with a survival of 35%-37%. Adults have the lowest survival rate of 27%-30%.^{45,46} ECPR is used in several scenarios of profound cardiovascular collapse: stabilization and maintenance of hemodynamics after cardiac arrest and the successful return of spontaneous circulation (ROSC) during in-hospital cardiac arrest (IHCA) and out-of-hospital cardiac arrest (OHCA). Several studies have reported ECLS use in 23%-41% of patients after CPR and ROSC. Compared to patients who were supported with ECLS in the absence of CPR, these groups had a two-fold increased risk of an unfavorable outcome.⁴⁷

Despite a higher mortality rate in patients placed on ECLS during CPR, several studies have shown a benefit of a 30-day survival up to 34%.⁴⁸ Time to ECMO from the initiation CPR has shown to be associated with the outcome while other reports find no difference in the outcome with CPR up to 60 minutes. Thus, adequacy of CPR is likely more important than the actual duration. Therefore, an assessment of the patient and a decision regarding the initiation of ECLS should be

performed by an experienced practitioner within 10-15 minutes of IHCA, with the assumption that the ECLS team and resources are available to initiate ECLS within 20-45 minutes.

The outcomes of patients with OHCA are historically poor, with survival in the range of only 10%-12%.^{39,49} However, a recent report from Australia noted a survival of 56% in out-of-hospital arrest patients who received bystander CPR and ECMO cannulation in the ED and a 60% survival in those with inpatient arrest.

Emerging Indications for ECLS

The successful use of ECLS in adult sepsis, sepsis-induced cardiomyopathy, and toxic shock syndrome has been reported in past decade.^{50,51} Recently, two large series have confirmed that ECLS should be considered in patients with refractory septic shock, demonstrating a survival rate of 23%-71%.^{36,52}

ECMO has been successfully used in patients with trauma,⁵³ severe drug intoxication,⁵⁴ and diffuse alveolar hemorrhage due to systemic disease.³⁷ It is considered the gold standard for rewarming following an accidental hypothermic cardiac arrest.^{55,56}

WEANING FROM ECMO

Weaning of VA ECMO is guided by improving hemodynamic echocardiography (TTE or TEE) at a reduced flow. Pulmonary artery catheters may also provide valuable information if present. Many patients require low doses of vasoactive agents to facilitate weaning. Careful assessment of biventricular function, hemodynamics, and the metabolic profile at a low flow or during a “clamp off” trial is mandatory. Clamping patients off of ECMO support provides the best indication of the adequacy of cardiopulmonary function. After some time (often 1-2 hours) at low flow (1 L) or clamped off from ECMO, if adequate hemodynamics, tissue perfusion, and gas exchange are obtained, decannulation is performed.⁵⁷

Weaning from VV ECMO should be initiated when the gas exchange and lung compliance begin to improve. Ventilator settings may be increased but remain at protective levels, and FiO_2 is increased to a maximum of 0.5-0.6. As the lung membranes are very efficient at removing carbon dioxide, the complete cessation of gas flow and “capping” of the lung membrane is required to fully evaluate the patient’s ability for gas exchange. Once the patient maintains stable gas exchange with minimal ECMO support and acceptable ventilator settings, ECMO can be discontinued.²² A recent international survey found that 16% of patients were removed from ECMO while not on a ventilator.

COMPLICATIONS

ECMO is highly invasive and has the potential for serious complications. The most common mechanical complication of adult respiratory ECMO is a failure of the oxygenator (16%), followed by cannula problems (7.7%). Bleeding and thrombosis remain the most common patient complications, and intracranial hemorrhage or thrombosis is the most devastating patient-related complication.⁹ Interestingly, complication rates are similar for respiratory or cardiac failure indications (Table 42-1). In a recent study of more than 1400 patients placed on VV-ECMO, the most frequent patient-related complication was hemorrhage.¹⁰ Cerebral infarction or hemorrhage occurred in 4%-6% of patients, with more than 20% of patients having confirmed documented infections. While circuit rupture rates have declined from 17% in the 1980s to less than 2% recently, the incidence of clot formation within the circuit has increased. Clinically relevant thrombosis was noted in 75% of postmortem exams, although clinicians identified only one-third of these events.

A recent meta-analysis of ECLS use for cardiac failure exhibited significant rates of ECLS-related complications.¹¹ Acute kidney injury was reported in 55% of patients, with 46% requiring renal replacement therapy (RRT). Major bleeding and significant infection occurred in

Complications of extracorporeal membrane oxygenation for treatment of cardiogenic shock and cardiac arrest: a meta-analysis of 1,866 adult patients. Ann Thorac Surg 2014;97(2):610-6.)

41% and 30% of patients, respectively. A significant proportion of patients developed complications related to vascular cannulation, including 17% with lower extremity ischemia, of which 10% resulted in compartment syndrome and fasciotomies and 4.7% required amputations of the lower extremities.

PEDIATRIC ECMO/ECLS

The application of ECMO to pediatric patients has become commonplace in many centers throughout the world. Current data on the diagnoses and outcomes of the over 50,000 neonates and children receiving ECMO is presented in Table 42-2. The largest growth of ECMO use in children remains in the cardiac failure population. Compared to 10 years ago, the use of ECMO as a bridge to transplant or long-term ventricular assist devices is now also viewed as a viable technique. Children undergoing ECMO during active cardiac arrest and resuscitation also form an increasingly larger group of patients, with an overall survival of 35%-40% over time.

One factor that is noted in pediatric ECMO is the increasing complexity of patients who receive ECMO support (Fig. 42-4).⁵⁸⁻⁶⁰ A review from the ELSO found that patients with comorbidities before ECMO increased from 18% to 47% between 1993 and 2007.⁵⁸ While such patients had decreased survival as compared to patients without comorbidities, 40%-50% survived to hospital discharge. Factors associated with increased mortality from this report are shown in Table 42-3. The willingness of clinicians to apply ECMO to groups previously shunned is also noted in the number of patients with an underlying malignancy who are now receiving ECMO support. Such patients now comprise 1% of the pediatric ECMO cases, an amount three times larger than in years past, with an overall survival to discharge of 48%.⁶¹⁻⁶⁴

Other factors that may relate to the expansion of ECMO to groups previously excluded may be the advent of new technology. The ELSO

| Treatment before 2001 | 1.22 | 1.03-1.44 |
| Age > 10 years | 1.37 | 1.10-1.71 |
| Ventilation > 14 days | 2.55 | 1.90-3.42 |
| VV ECMO | 0.66 (vs. VA) | 0.56-0.77 |

(Data from Zabrocki, LA, Brogan, TV, Statler, KD, Poss, WB, Rollins, MD, Bratton, SL. Extracorporeal membrane oxygenation for pediatric respiratory failure: survival and predictors of mortality. Crit Care Med 2011;39(2):364-70).

registry has found that approximately two-thirds of children with respiratory failure (>30 days of age) now receive VV support. While venovenous ECMO requires adequate cardiac function, many patients with pre-ECMO vasoactive needs often have a reversal of mild to moderate cardiac dysfunction once improved oxygen delivery and reduced mechanical ventilator settings occur with ECMO initiation. The advantages of VV support in children remain similar to adults, and while the long-term benefits of this approach over venoarterial access remain to be proven, initial data suggest that VV support is associated with improved survival and decreased complications.⁶⁴

As in adults, universally validated criteria for ECMO initiation do not exist. A consensus conference on pediatric acute respiratory distress syndrome was recently held and the results published. One severity tool, the oxygenation index, was recommended as a serial measure of the severity of lung injury. While OIs of >40 were often used in the past, new data suggest that mortality increases at levels >16. When combined with another variable of lung injury, pulmonary dead space, OIs of >16 with dead space of >23% resulted in an observed mortality risk of 53% (Khemani, R., personal communication). These findings, combined with the increased ease of applying ECMO, have led to a discussion as to whether ECMO should be applied at OI severity scores

much lower than in the past. A case-by-case discussion of the potential benefit of ECMO versus risk is also practiced.

Another change in pediatric ECMO is that survival based on the pre-ECMO duration of mechanical ventilation is equivalent up to 14 (and even 21 in one series) days, as opposed to 7 days historically.⁵⁸ The potential reversibility of the underlying injury is now a larger factor in ECMO candidacy than pre-ECMO ventilator duration. In a similar fashion, prolonged duration of ECMO for weeks or months is also acceptable if the process is thought to be reversible, or if the patient is being bridged to a lung or heart transplant. Unlike adults, young children can grow new alveoli and overcome lung damage. Prolonged ECMO duration and an emphasis on rehabilitation have led to the latest change in support techniques, that of maintaining the patient in an awake and mobile state. However, managing infants and children in such a manner has unique difficulties. These difficulties are often highlighted during the emergence phase from heavy levels of narcotics, benzodiazepines, and a potential neuromuscular blockade that may have been in place in the pre-ECMO period. Transitioning to an awake and interactive status requires commitment and collaboration among bedside medical staff, family, and ancillary services (e.g., child life and physical therapy). The use of less sedating medications (e.g., dexmedetomidine), while expensive, may be helpful. As with adults, many centers are advocating extubation and ambulation of children during ECMO support, while others choose to maintain some level of mechanical ventilator support (often using spontaneous breathing modes but focusing on nontoxic levels of support) via a tracheal tube or tracheostomy. Percutaneous tracheostomy can be performed safely at the bedside if the medical staff does not prefer extubation and the ECMO course is likely to be long. Enteral feeding is advocated, as is physical therapy to maintain muscle strength.

Long-term follow-up to identify deficiencies and institute early intervention is required. Reports indicate that up to 50% of children surviving ECMO have neurodevelopmental abnormalities, although severe disability is rare. Behavioral concerns (ADD, learning disabilities), slightly lower IQ, and hearing loss appear to be the most common.

ETHICAL CONSIDERATIONS

Ease of application and accessibility are increasing in the patient populations who are placed on ECMO, and the durability of systems now allow prolonged support. Determining futility is difficult, and long-term outcomes, resource use, and efficacy remain issues to be resolved in the future.⁶⁵

KEY POINTS

1. Venovenous extracorporeal membrane oxygenation (ECMO) is used in patients with isolated respiratory failure and relies on preserved cardiac function, whereas venoarterial ECMO provides both respiratory and cardiac support and is frequently referred to as extracorporeal life support (ECLS).
2. Venovenous respiratory ECMO is successfully used in adult patients with severe refractory ARDS, in patients with end-stage lung disease as a bridge to transplant, and in cases of severe primary graft dysfunction (PGD) following lung transplantation.
3. Low-flow extracorporeal CO₂ removal systems (ECCOR) are used in severe hypercarbic forms of ARDS and in patients with COPD exacerbation.
4. Venoarterial cardiac ECLS is used as a bridge system to recovery, ventricular assist device (VAD), or heart transplant in patients with cardiogenic shock due to ACS, myocarditis, or end-stage heart failure, with best survival in patients in the myocarditis group.
5. ECPR (extracorporeal cardiopulmonary resuscitation) is a powerful tool used to stabilize patients in refractory cardiac arrest; however, survival remains low.
6. Complications of ECMO are not uncommon and include systemic infections, cerebrovascular accidents (CVAs) both hemorrhagic and embolic in origin, bleeding, and limb ischemia. Technical complications have declined over time.
7. Well-defined criteria for appropriate patient selection for ECMO initiation do not exist at present.

Critically ill patients typically have anorexia and are frequently unable to take oral diets. Therefore, micronutrients and macronutrients should be prescribed as enteral or parenteral nutrition.¹

The catabolic response of critical illness is characterized by inflammatory and endocrine stress responses that may induce increases in resting energy expenditure (REE) and urinary nitrogen excretion.²

Nutritional intake may be insufficient and lead to accumulated energy and protein deficits. This can result in a reduction of the lean body mass (LBM) to an extent of 1 kg per day.³ Both low admission LBM, severe skeletal muscle wasting, and ICU-acquired weakness are associated with a prolonged need for mechanical ventilation and increased infectious morbidity and mortality rates.^{4,5}

Anorexia is likely a maladaptive response as animal and human studies have shown trophic effects of enteral nutrients on gut mucosa integrity and improved outcomes.⁶

Nutritional support for adult ICU patients aims at reducing energy and protein deficits without inducing overfeeding, sufficient micronutrient intake, and preserving gut integrity. Several large nutrition trials with high-quality data have led to some consensus. However, many controversies persist.^{6,7}

NUTRITIONAL RISK ASSESSMENT

Most nutritional assessment instruments, such as the MNA, SGA, SNAQ, NRS-2002, and MUST scores have not been developed for ICU patients and rarely have been specifically validated.⁸

A novel method, the NUTRITION Risk in the Critically ill (NUTRIC score) has been made available.⁹ A conceptual model links starvation, inflammation, nutritional status, and outcomes (Fig. 43-1). Low scores (0-4) predict a low malnutrition risk, and high scores (5-9) identify patients with increased ventilation duration and mortality that are most likely to benefit from nutrition therapy (Table 43-1).

Patients with a higher body mass index (kg/m^2 ; BMI) demonstrate better ICU and hospital survival due to poorly understood mechanisms.¹⁰ Low skeletal muscle area, as assessed by CT scan, is a risk factor for mortality in ventilated patients, independent of gender and APACHE-II score. Moreover, muscle mass was a primary predictor of mortality, while BMI was not.¹¹ Preserving LBM is a primary target of nutritional therapy.

REFEEDING SYNDROME

Refeeding syndrome refers to biochemical and clinical symptoms, as well as metabolic abnormalities due to shifts in electrolytes and fluid imbalance in malnourished patients undergoing refeeding by oral, enteral, and/or parenteral feeding.¹²

It is characterized by low concentrations of predominantly intracellular ions; phosphate, magnesium, and potassium, in addition to abnormalities in glucose metabolism, sodium levels, and water balance associated with morbidity and mortality.¹³ Thiamine deficiency can also occur.¹⁴

The incidence of refeeding syndrome is unknown due to the lack of a universal definition. Plasma electrolytes and glucose should be measured before feeding and any deficiencies corrected during feeding. Whenever marked hypophosphatemia occurs after the start of feeding, intake should be reduced to 500 kcal per day for 48 hours.^{15,16}

ENTERAL NUTRITION

Tube feeding or enteral nutrition (EN) is administered as a special liquid food mixture containing proteins, carbohydrates, fats, vitamins, and minerals, through a tube into the stomach or small bowel.

Feeding Tubes

Nasogastric or naso-enteral tubes are placed into the stomach or bowel through the nose. To prevent sinusitis or nasal decubital ulceration, orogastric and oro-enteral tubes are also used. A tube directly placed through the skin into the stomach or bowel is called a *gastrostomy* or *jejunostomy*.

Nasogastric tubes may be used depending on composition: PVC tubes up to 10 days, PUR up to 6-8 weeks, and silicone tubes for 6 weeks to 3 months.

Blenderized Tube Feeds

Low-cost blenderized tube feeds ("home brew") are used in some parts of the world. Macronutrient content is usually highly variable, often conflicting with daily recommendations.¹⁷ Moreover, there is a high contamination risk, physical and chemical instability, and high osmolality and viscosity, potentially enhancing intolerance.

Commercially Available Tube Feeds

Tube feeds are available as canned powder to dissolve, liquid containing glass bottles, or self-collapsible packages. Closed feeding systems involve the use of sterile feeding containers that are spiked with feeding sets. Closed feeding systems use connectors that prevent a connection to intravenous lines and reduce the contamination risk, and the hanging time can be increased up to 24 hours. Higher contract price and increased waste of closed systems leads to higher daily costs. However, after adjusting for nursing time and feed contamination costs, the total costs are lower.¹⁸

Compositions of Tube Feeding

Nutrient concentrations of formulas vary from 1.0-2.0 kcal/mL. Calorically dense formulas are used in patients requiring fluid restriction. Polymeric high-protein formulas have higher protein to nonprotein energy ratios and aid in achieving protein requirements in obese patients while preventing energy overfeeding. There is no evidence that hydrolyzed protein (peptide-based) formulas are superior with respect to tolerance, absorption, or outcome.¹⁹

Fibers

There are feeds with and without fibers. Sources of fiber in EN include soluble and insoluble fibers. Soluble fibers (e.g., pectin and guar) are fermented by colonic bacteria and enhance colonic sodium and water absorption to treat EN-associated diarrhea. Insoluble fibers (e.g., soy polysaccharide) increase fecal weight and peristalsis and decrease the fecal transit time.²⁰ Frequently, mixtures of fibers are used.

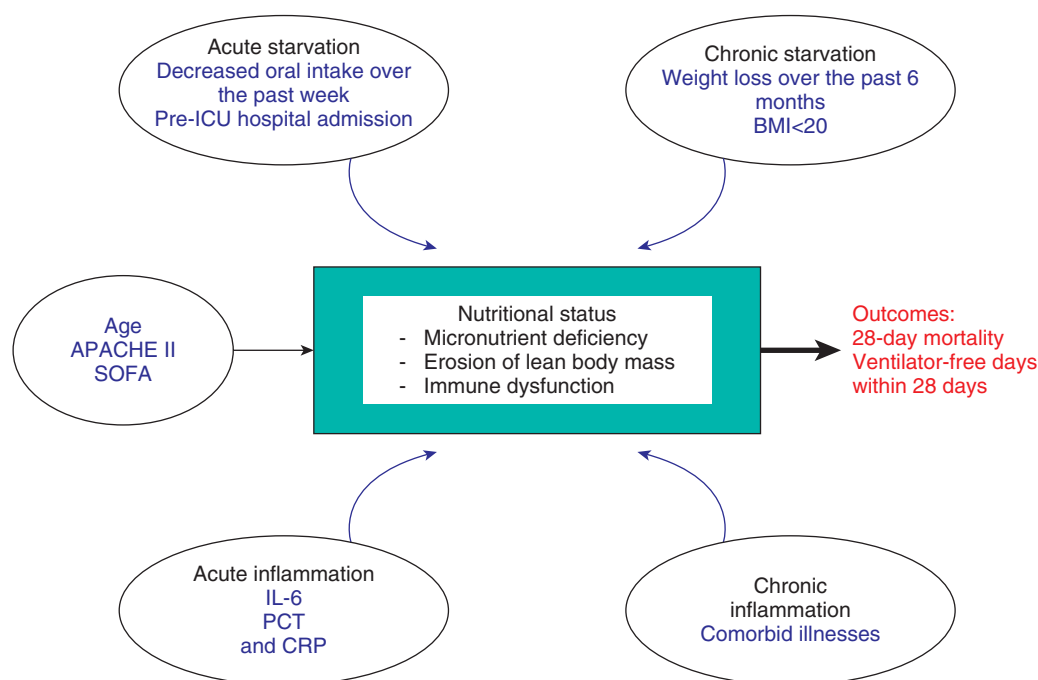

FIGURE 43-1 ■ Several factors are involved in the nutritional status of the critically ill at the time of ICU admission. Nutritional status is related to chronic and acute starvation, acute and chronic inflammation and disease severity. (From Heyland DK, Dhaliwal R, Jiang X, Day AG. Identifying critically ill patients who benefit the most from nutrition therapy: the development and initial validation of a novel risk assessment tool. *Critical Care*. 2011;15(6):R268.)

TABLE 43-1 Modified* Nutric Score Variables

The NUTRIC Score is designed to quantify the risk of critically ill patients developing adverse events that may be modified by aggressive nutrition therapy. The score, of 1-9, is based on five variables that are explained below.

| VARIABLE | RANGE | POINTS |
|-------------------------------------|-------|--------|
| Age (years) | <50 | 0 |
| | 50-75 | 1 |
| | >75 | 2 |
| APACHE-II score (points) | <15 | 0 |
| | 15-20 | 1 |
| | 20-28 | 2 |
| | >28 | 3 |
| SOFA-score (points) | <6 | 0 |
| | 6-10 | 1 |
| | >10 | 2 |
| Number of comorbidities | 0-1 | 0 |
| | >2 | 1 |
| Days from hospital to ICU admission | 0-1 | 0 |
| | >1 | 1 |

*IL-6 was part of the original scoring system (acute inflammation); however, it was often not routinely available as it contributed very little to the overall prediction of the NUTRIC score. The modified score is depicted.

From Heyland DK, Dhaliwal R, Jiang X, Day AG. Identifying critically ill patients who benefit the most from nutrition therapy: the development and initial validation of a novel risk assessment tool. *Critical Care*. 2011;15(6):R268.

Disease-Specific Feeding Formulas

Renal formulas have lower protein concentrations, as well as potassium and phosphate levels. Hepatic formulas have increased amounts of branched-chain amino acids (e.g., valine, leucine, and isoleucine) and reduced amounts of aromatic amino acids (e.g., phenylalanine, tyro-

sine, and tryptophan). Diabetic formulas have lower carbohydrate, higher fat content, and variable types of carbohydrates (e.g., oligosaccharides, fructose, cornstarch, and fiber). In pulmonary formulas, some carbohydrate calories are substituted with fat calories to limit CO₂ production and improve ventilation. ARDS formulas combine antioxidants with borage and fish oils, to supplement gamma-linoleic acid (GLA), and eicosapentanoic acid (EPA).

In patients with chyle leakage, low-fat or medium chain triglycerides (MCT), or enriched feeds are recommended. MCT does not require lymphatic transport.

Overall, for all disease-specific feeding formulas, strong evidence to improve outcome is lacking.²¹

Allergies

The majority of adverse reactions to food are nonimmunologic in origin, with lactose intolerance being the most common. Documented food allergies in adults are likely lower than 8%-10%, and most enteral feeds are gluten-free. For specific allergies, soy-free, casein-free, whey-free, and egg-free feeds are available.

Contraindications to Enteral Nutrition

In general, EN is safe when contraindications are carefully reviewed (Box 43-1). They are related to obstruction, bowel perforation, and ischemia. Many critically ill patients are at risk of splanchnic hypoperfusion due to circulatory redistribution. It is essential to provide adequate fluid therapy before commencing EN. There is no definition of hemodynamic stability associated with safe enteral feeding. However, retrospective data show that early EN in patients on vasopressor treatment is safe and improves outcome.²¹ Patients should have stable blood pressures without the need to increase vasopressors, with acceptable ScVO₂ and/or plasma lactate levels or other indicators of adequate blood flow. For most patients this will be within 6-12 hours after admission, still meeting the window of early EN (24-28 hours).

Timing of Initiation

By definition, early EN is initiated within the first 24-48 hours after hospital admission. ICU admission is considered to be the starting moment for ICU patients. Observational studies show that early EN is superior to late initiation (>48 hours) and is therefore recommended in the guidelines.²² The practical inability to initiate early EN may reflect the severity of illness. Therefore, large randomized trials on early EN versus delayed nutrition are warranted.

BOX 43-1 Contraindications to Enteral Nutrition

ABSOLUTE CONTRAINDICATIONS

- Intestinal obstruction
- Ongoing splanchnic ischemia
- Small bowel fistulas that cannot be bypassed by the feeding tube
- Hemodynamic instability*

RELATIVE CONTRAINDICATIONS

- Active gastrointestinal hemorrhage
- Early stages of short bowel syndrome
- Severe malabsorption

*Enteral nutrition may worsen ischemia due to hypoperfusion of the gut and lead to necrosis and bacterial overgrowth.

Full Versus Trophic Enteral Nutrition

The optimal dose of nutritional support is heavily debated. Permissive under-, trophic, trickle, and hypocaloric feeding are frequently used and confusing.

Permissive underfeeding suggests a lower nutritional intake (e.g., calories, proteins, and micronutrients) is acceptable. Hypocaloric feeding implies that only energy intake is lower. Trophic feeding has no clear definition, although it is accepted to represent an enteral intake of 10-20 mL/h or 500-1000 kcal/day.

Recent trials on trophic and full nutritional support were summarized and did not demonstrate benefits of either strategy, suggesting that trophic feeding could be sufficient (Table 43-2).²⁴ However, most studies included relatively young, well-nourished (high BMI) patients with low nutritional risk (NUTRIC score < 5). In the only trial with a higher nutritional risk, trophic feeding was associated with more infections. Functional outcomes in all studies were not investigated, although the long-term outcomes have been shown to be associated with feeding adequacy.²⁵

Stoppages

Interruptions in feeding for various reasons are frequent, resulting in intakes less than the prescribed amounts. Administering target volumes over 20 hours to circumvent this problem or to increase infusion rate after stoppages can be recommended.²⁶

TABLE 43-2 Randomized Trials on Trophic and Full Nutritional Support

| STUDY | YEAR | PATIENTS (N) | BMI (KG/M ²) | NUTRITIONAL RISK | MEAN DAILY CALORIES | MEAN DAILY PROTEINS | OUTCOME |

*Based on mean study data for both groups, the modified NUTRIC-score was estimated.

Adapted from McClave SA, Martindale RG, Vanek VW, McCarthyM, Roberts P, Taylor B, et al. Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient: Society of Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.). JPEN Parenter Enteral Nutr. 2009;33(3):277-316. Table 2.

Gastric Residual Volume

The increased gastric residual volume (GRV) amount aspirated from the stomach following administration of feed represents feeding intolerance. Risk factors for delayed gastric emptying include gastroparesis, diabetes mellitus, gastric outlet obstruction, (postoperative) ileus, trauma, or sepsis, and medications affecting gastric motor function (e.g., opioids). Aspiration of gastric contents should be prevented, although the GRV thresholds are non-evidence based. Recommendations have gradually increased up to 500 mL/6 h, and GRV can be reinfused or discarded. Discarded GRV reduces feeding efficacy.

Proton pump inhibitors reduce gastric secretions.²⁷ Prokinetic medications are used to improve gastric emptying, such as metoclopramide (e.g., 4 × 10 mg and erythromycin 2 × 200 mg) either alone or combined. They are safe when QTC intervals are monitored and used for up to 7 days, and tachyphylaxis is common.²⁸ Two trials demonstrated that the omission of GRV measurement does not increase the aspiration incidence. Moreover, allowing a large GRV increases the amount of feeding administered. To abandon the GRV measurement is debated, and if all strategies fail, a postpyloric feeding tube can be inserted as often as small intestinal functions are normal.²⁹

Postpyloric Feeding

Immediate postpyloric feeding may facilitate the early increase of EN, and evidence of superiority is lacking. However, the reduced aspiration risk has been clearly demonstrated.³⁰ Postpyloric tubes are placed by duodenal endoscopy or using electromagnetic tube placement or self-advancing nasal-jejunal devices. Selection of modality, timing, and success of positioning are related to patient factors, operator experience, and logistics. Criteria to monitor postpyloric feeding are provided (Box 43-2) as monitoring jejunal feeding is complex.

Complications of Enteral Nutrition

Most complications associated with EN are minor, but some can be serious. Complications can be categorized into problems encountered during the placement of tubes (e.g., tracheal/pulmonary misplacement and epistaxis) and during delivery: clinical and metabolic problems (e.g., refeeding syndrome, high GRV, vomiting, aspiration, diarrhea, azotemia, hypernatremia, and dehydration or hyperglycemia), and nutritional problems (e.g., tube obstruction and bacterial contamination).

Aspiration

There is no consistent relationship between gastric residual volumes and aspiration. Aspiration may occur with low GRV; it occurs signifi-

cantly more often when the volumes are high.³¹ Head-of-bed elevation can be recommended, although whether 45° head-of-bed elevation is superior to 25°-30° elevation remains unproven.

Routine GRV monitoring in ventilated patients to prevent aspiration is debatable as omitting measurements does not transfer into higher ventilator-associated pneumonia rates.³²

Diarrhea

Critically ill patients may develop diarrhea for various reasons (Box 43-3). During the first 14 ICU days, at least 1 day of diarrhea was observed in 14% of patients. Delivering >60% of the energy target by EN, antibiotics, and antifungal drugs are risk factors.³³ Of the diarrhea episodes, 89% lasts 4 days or less. EN *per se* was not a risk factor, while anecdotal improvements have been reported when using fiber-enriched nutrition or hydrolyzed protein formulas.³⁴

Constipation

The prevalence of lower gastrointestinal tract paralysis leads to an increased fecal transit time; (>5 days) is common and in some series up to 90% is seen. Opioid administration is associated with delayed defecation. Prophylactic or therapeutic laxatives and/or fiber-enriched enteral nutrition (prebiotics) is recommended. Both lactulose and polyethylene glycol are more effective in promoting defecation than the placebo. Early defecation is associated with a shorter length of stay.³⁵

Protocols

Evidence-based nutrition protocols designed to improve enteral feeding have been shown to improve feeding adequacy and outcome.^{36,37} Developing a protocol is recommended (Fig. 43-2).

BOX 43-3

Common Causes of Diarrhea in Critically Ill Patients

MEDICATION

Antibiotics
H₂-receptor antagonists, antacids
Drugs: significant amounts of sorbitol, magnesium, or hypertonic medications
Laxative use (unintended)

GASTROINTESTINAL DYSFUNCTION

Gastric or small bowel resection
Inflammatory bowel disease
Pancreatic insufficiency
Radiation enteritis
Sprue
Protein-losing gastroenteropathies
Bowel impaction (paradoxical)

MALNUTRITION

Hypoproteinemia
Micronutrient deficiencies

ENTERAL NUTRITION-ASSOCIATED

Excessive feeding rate, concentration, volume, or osmolality
Adaptation in malnourished patients or those whose gastrointestinal tract has not been used recently
Intolerance or allergy to feeding formula

INFECTION

Clostridium difficile enterocolitis
Opportunistic gastrointestinal infection
Significant amounts of contaminated feeding formula
Altered gastrointestinal flora

ENDOCRINE DYSFUNCTION

Diabetes mellitus
Hyperthyroidism
Hypocortisolism

BOX 43-2 Monitoring Postpyloric Feeding*

MONITOR

- GRV volume and aspect
- Abdominal distention
- Fecal transit time
- Intra-abdominal pressure (optional)

CRITERIA TO STOP POSTPYLORIC FEEDING

- Major feeding admixture in gastric aspirate suggesting back-flow
NB: gastric aspirate without tube feed admixture is not a reason to stop irrespective of volume
- Major abdominal distention
- Uncontrolled vomiting
- Obstruction ileus
- Intraabdominal pressure > 20 cm H₂O
- Severe diarrhea

*Before starting postpyloric feeding, check for general contraindications to enteral nutrition (Box 43-1)

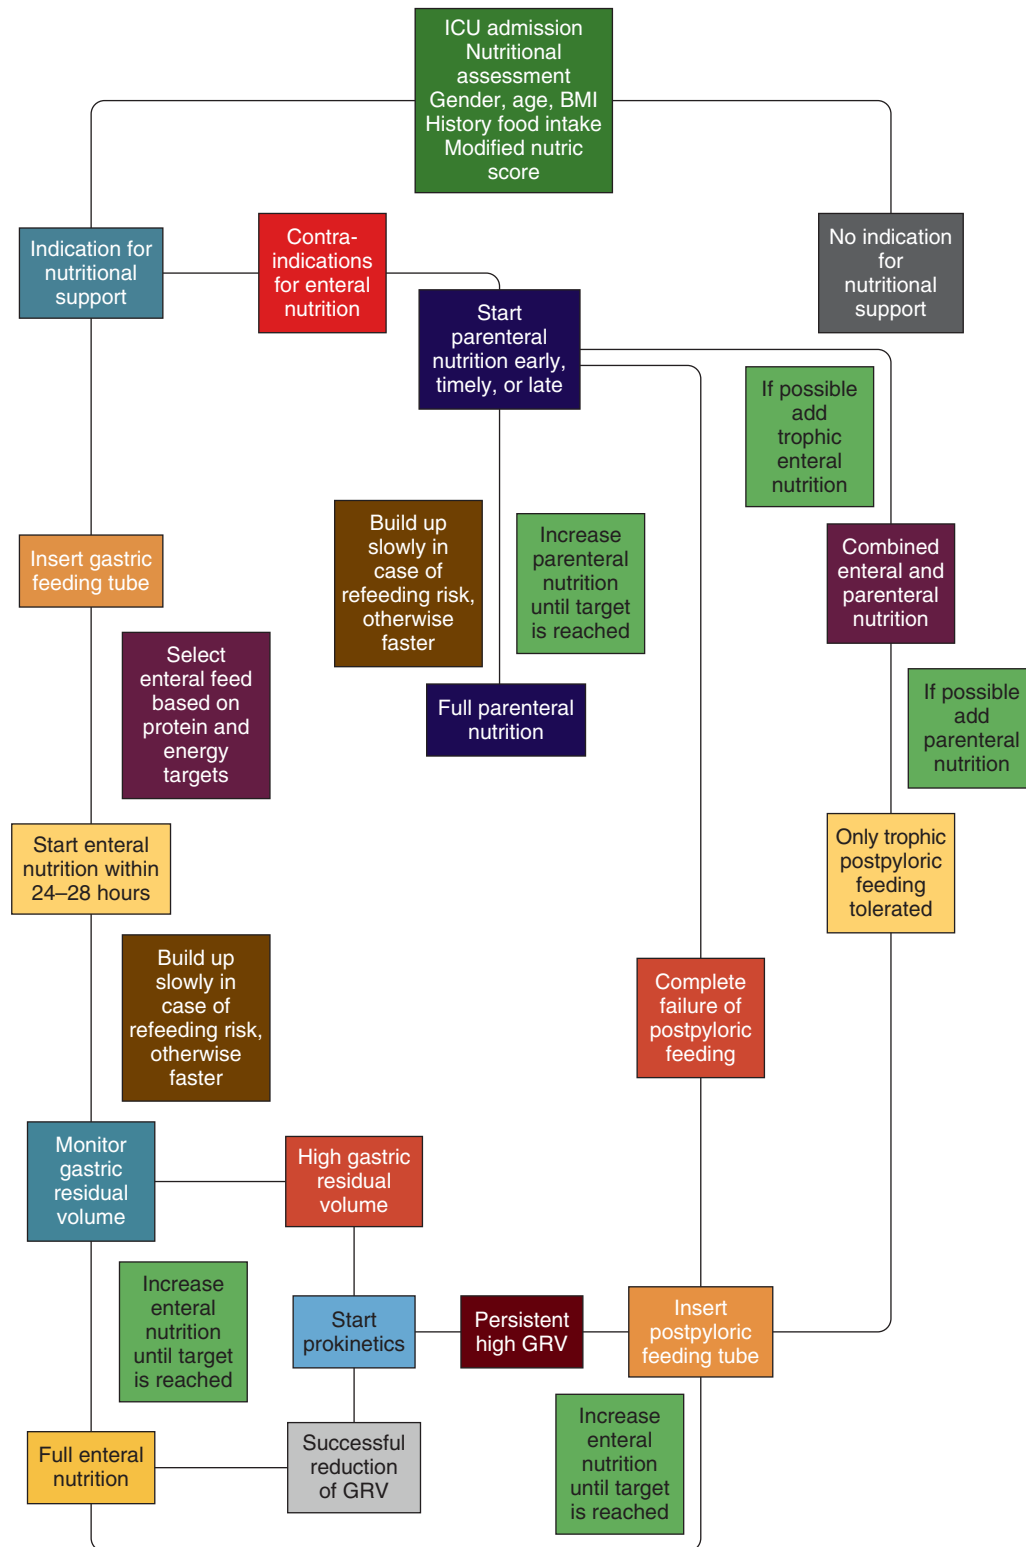

FIGURE 43-2 ■ Nutritional support flow chart.

PARENTERAL NUTRITION

Total parenteral nutrition (TPN) supplies all daily nutritional requirements by the parenteral route (via a central venous catheter or venous peripherally inserted central catheter [PICC-line]). Partial or supplemental parenteral nutrition (SPN) aims to close the gap in the intake when EN does not reach the targets.

Composition

The optimal PN composition depends on the clinical situation, energy, and protein needs, as well as electrolyte abnormalities and the risk of fluid overload.

The liquid food mixture of standard PN comprises amino acids (apart from glutamine for reasons of stability), carbohydrates (e.g.,

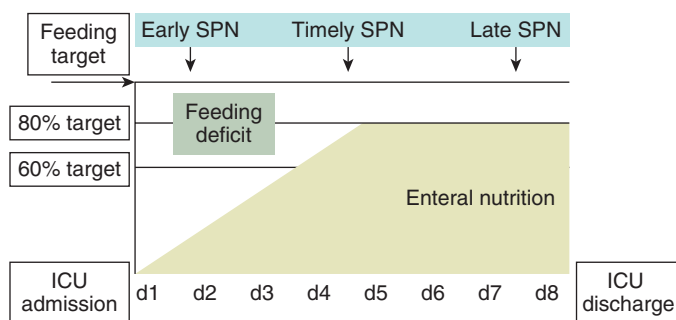

FIGURE 43-3 ■ Timing of supplemental parenteral nutrition to prevent feeding deficit.

dextrose/glucose), and lipid emulsions (e.g., soybean, olive or fish oil-based) and is infused from multi-chamber or single-chamber sterile infusion bags.³⁸ Trace elements are added to meet daily recommended allowances. In the absence of EN vitamin, K supplementation among other vitamins is important. In the case of hepatic complications (hyperbilirubinemia) interruption of lipid emulsion is recommended, and the optimal lipid emulsion still is debated. The omega-3 fatty acids in the fish oil have antiinflammatory effects, omega-9 fatty acids in the olive oil have neutral immune effects, and omega-6 fatty acids in soybean oil are proinflammatory. Soybean-based emulsions should be avoided.⁶

Timing of SPN Initiation

Nutrition guidelines present divergent advice regarding the timing of SPN ranging from early SPN (<48 h after admission) to postponing SPN until day 8 after ICU admission. Others have studied starting SPN after 3 days (timely; Fig. 43-3).

One RCT found a higher percentage of living ICU discharge at day 8 in the late SPN group, but there were no differences in ICU and in-hospital mortality. No other RCT found differences in ICU or in-hospital mortality rates. Contradicting results were found for ICU and hospital length of stay, infection rates, nutrition targets, duration of ventilation, glucose control, duration of renal replacement therapy, muscle wasting, and fat loss.

It is reasonable to assume that there are no clinically relevant benefits of early SPN. Considering infectious morbidity and potential slower organ failure resolution, and higher acquisition costs, the early administration of SPN cannot be recommended.³⁹

In severely malnourished patients, early SPN should be considered, and initiation can be delayed for 5-8 days in others.⁴⁰

Complications

Several complications are related to PN use (Box 43-4), and most can be prevented by catheter sepsis prevention and the close monitoring of glucose and electrolytes, fluid status, triglycerides, as well as liver and renal laboratory tests.

Parenteral Nutrition Versus Enteral Nutrition

EN was considered to be superior over PN. The Calories trial that compared 2400 patients randomized into EN or PN, changed this assumption.⁴¹ No differences in infections and mortality were found, and less vomiting and hypoglycemia were observed during PN. No differences in caloric intake were found to be due to the build-up of parenteral intake. Possibly due to better glucose control, preventing overfeeding and better central catheter care complications were similar to EN. EN remains a first-line therapy, but in cases that targets cannot be reached, it is safe to commence PN.

BOX 43-4 Complications of Parenteral Nutrition

CATHETER-RELATED

- Bleeding
- Pneumothorax
- Central line-associated bloodstream infection
- Obstruction
- Thrombosis, embolism

METABOLIC

- Refeeding syndrome
- Overfeeding
- Glucose abnormalities (hyperglycemia or hypoglycemia)
- Hyperlipidemia (hypertriglyceridemia)
- Liver dysfunction (increased transaminases, bilirubin, and alkaline phosphatase)
- Hepatomegaly
- Hyperammonemia
- Abnormalities of serum electrolytes and minerals
- Vitamin and mineral deficiencies
- Elevated BUN

CIRCULATORY

- Volume overload

ADVERSE REACTIONS

- Dyspnea
- Cutaneous allergic reactions
- Nausea
- Headache
- Back pain
- Sweating
- Dizziness

GALLBLADDER-ASSOCIATED

- Cholelithiasis
- Gallbladder sludge
- Cholecystitis (acalculous)

CALORIC REQUIREMENTS

Energy requirements in critical illness are unknown. Underfeeding (<80% of energy target) and cumulative energy deficit and overfeeding (>110% of target) are associated with increased morbidity (e.g., infections) and mortality. An optimum energy intake is estimated at 85% of the REE target.⁴² This lower optimum may result from endogenous energy production that cannot be abolished by providing energy.

Formulas to Estimate Energy Expenditure

Energy requirements are estimated based on patient characteristics before admission. However, requirements differ for each patient and day and should be preferably adjusted according to indirect calorimetry, although not widely available and often technically difficult or impossible to apply. Data from 160 variations of 13 predictive equations compared with indirect calorimetry measurements demonstrated 38% underestimated and 12% overestimated energy expenditure (>10%). Differences from minus 43% to 66% above indirect calorimetry values in individual patients were observed.⁴³

Guideline Recommendations for Daily Energy Intake

International societies have recommended intakes ranging from 20-25 kcal/kg per day in the acute phase, and 25-30 kcal/kg in the recovery phase. Additionally, it was suggested to prescribe hypocaloric feeding in critically ill obese (BMI > 30 kg/m²) patients, 60%-70% of the target energy requirements, or 11-14 kcal/kg of the actual body weight or 22-25 kcal/kg of the ideal body weight.^{1,44}

Indirect Calorimetry

Using a metabolic cart, REE can be measured with indirect calorimetry by measuring oxygen consumption (VO_2) and carbon dioxide production (VCO_2). Every liter of oxygen consumed is equivalent to 5 kcal. Weir introduced an equation to calculate REE:

$$\text{REE} = [\text{VO}_2 (3.941) + \text{VCO}_2 (1.11)] 1440 \text{ min/day}.$$

REE provides better energy targets than formulas, and the respiratory quotient (RQ) (CO_2 -production/ O_2 -consumption) is indicative of substrate use. RQ is 1.0 when the fuel is a carbohydrate, 0.8 for protein, and 0.7 for fat; normal RQ is 0.80. $\text{RQ} > 1.0$ may indicate overfeeding. Inaccuracies can arise from air leaks (e.g., circuit or pneumothorax). As O_2 sensors are inaccurate at the higher FiO_2 levels (>0.6) application in pulmonary failure is limited. Additionally, high PEEP levels of circuit compressibility cause volume changes and measurement errors.

The Tight Calorie Control Study (TICACOS), involving 130 ventilated patients, compared EN with an energy target determined by indirect calorimetry or $25 \text{ kcal/kg}^{-1}/\text{day}^{-1}$ and showed that indirect calorimetry leads to higher mean energy and protein intake, resulting in a trend toward improved hospital mortality. However, the duration of ventilation and ICU stay was increased.⁴⁵ The uptake of metabolic carts is emerging, and studies are ongoing.

Nonnutritional Calories

Typically, nutritional calories are evaluated; however, some calories may go unnoticed.

Glucose and dextrose-containing infusions and drugs, propofol (lipid-based), and trisodium citrate used for extracorporeal circuit anticoagulation during renal replacement therapy provide non-nutritional caloric intake, potentially inducing overfeeding.

PROTEIN REQUIREMENTS

Critical illness cause increased protein turnover and the loss of LBM. There is growing evidence demonstrating the importance of protein and amino acid provisions, and it is likely that nutritional proteins have an impact on the preservation of muscle mass, resulting in better patient outcomes.⁴²

Guideline Recommendations for Daily Protein Intake

Several nutritional societies provide slightly different recommendations; however, they can be summarized as to provide 1.2–2.0 g protein/kg if the BMI $< 30 \text{ kg/m}^2$, 2 g/kg ideal body weight if BMI 30–40 kg/m^2 , and 2.5 g/kg ideal body weight if the BMI $> 40 \text{ kg/m}^2$.^{2,121,44}

SPECIFIC MACRONUTRIENTS

Enriched or supplemented (par)enteral nutrition with supposed immune-modulating macronutrients (e.g., glutamine, arginine, and fish oil) have frequently been studied.³⁴ Pharmaconutrition suggests that specific nutritional components may exert pharmacologic effects to modulate the immune response.

Contrasting international recommendations, the MetaPlus trial demonstrated no effect of a cocktail of macronutrients (e.g., glutamine and fish oil) and micronutrients (e.g., selenium, vitamins C and E, and zinc) on the primary endpoint of infections.⁴⁶ Moreover, increased long-term mortality among medical patients was observed. In the REDOXs trial, no clinical benefit of glutamine and antioxidants was found, and a trend toward increased mortality at 28 days, as well as significant increases in-hospital and 6-month mortality in glutamine-supplemented patients, was found.⁴⁷

Since then, the safety of immune-modulating ingredients has been questioned. Benefits are limited or absent, and potential harm is involved. Use of unbalanced compositions is not recommended.⁴⁸

Glutamine

Glutamine is the most abundant plasma amino acid. In critical illness, plasma levels can be low. However, this is not always the case. Non-essential amino acids can be synthesized from other amino acids. Low levels in ICU patients are considered to be conditionally deficient, too low for the actual condition disease state. As low admission plasma glutamine was associated with increased mortality, supplementation was considered.

Positive effects are based on results from older, smaller, and mainly single-center studies. Recent studies have challenged the conditional deficiency hypothesis, both in mechanistic studies and in recent randomized trials (MetaPlus and REDOXs). Low levels could potentially reflect an adaptive response. Glutamine supplementation may only be considered while monitoring plasma levels and should be avoided as serious safety issues are involved.⁴⁹

Arginine

Another amino acid considered to be conditionally deficient is arginine. Data from 30 trials in 3000 patients after major surgery exhibit reduced infectious morbidity of arginine supplementation and a reduced length of stay. Before surgery, 5–7 days of arginine (12–15 g/day) may be beneficial. However, harm was observed in severe sepsis patients. Excessive nitric oxide production increasing mortality risk was the suggested mechanism. For sepsis patients, arginine-supplemented EN should be avoided.³⁴

Fish Oil

We lack studies showing associations of low baseline EPA and docosahexaenoic acid (DHA) levels and outcome. Smaller studies combined borage and fish oils (GLA/EPA) with antioxidants in ARDS, suggesting a benefit.²¹ The large OMEGA-EN trial (e.g., omega-3 fatty acids, EPA, DHA, GLA, and antioxidants) in ARDS patients was prematurely terminated for not reducing ventilator-free days and a higher 60-day in-hospital mortality trend ($P = 0.054$).⁵⁰ At present, it is unclear whether fish oil confers benefits and does not increase harm.

SPECIFIC MICRONUTRIENTS

The exact recommended daily allowances (RDAs) for antioxidants, trace elements, and vitamins in ICU patients are not known. Many patients have low admission plasma levels. During the ICU stay, this may worsen as RDAs are only available in 1500 mL of EN, and many patients have lower intakes. In PN, trace elements and vitamins must be added. However, whether supraphysiological dosages should be prescribed is inconclusive.

Antioxidants and Trace Elements

A meta-analysis of 21 RCTs on combined antioxidant supplementation showed significant reductions in mortality, ventilation duration, and a trend toward reduction in infections with no effect on ICU or hospital LOS. Most of the included RCTs were small studies (<100 patients), which were inadequate to detect important effects on mortality. The positive signal emerges only after statistically aggregating these smaller trials.⁵¹ In an unadjusted analysis, a recent retrospective study suggests an increased mortality associated with selenium supplementation.⁵²

Vitamins

Few data are available via vitamin supplementation in ICU patients; however, whether low plasma levels reflect deficiency is not known. Hyperlactatemia may reflect thiamine deficiency, and supplementation is recommended.⁵³ Supplementation may also be indicated in case of alcohol abuse, severe malnutrition, or refeeding risk.

Vitamin D supplementation was studied using high-dose supplementation (540,000 IU followed by monthly doses of 90,000 IU for 5

months). No effect on hospital LOS, hospital mortality, or 6-month mortality was found. Lower hospital mortality was observed in severe vitamin D deficiency (≤ 12 ng/mL), requiring further study. Remarkably, many patients on high-dose supplementation did not exhibit normalized plasma levels of 25-hydroxyvitamin D.⁵⁴

There is a lack of dose-finding studies for most vitamins in critically ill patients. Moreover, we do not know whether normalizing plasma levels translates into a better outcome.

■ PREBIOTICS AND PROBIOTICS

The World Health Organization has defined probiotics as “live microorganisms, which confer a health benefit on the host.”⁵⁵ Prebiotics (fibers) are food for probiotics that are nondigestible by humans. Prebiotics stimulate the growth of beneficial bacteria. Symbiotic supplements contain both probiotics and prebiotics.

Critical illness leads to alterations of the gut microbiota, leading to a loss of commensal flora and the overgrowth of potentially pathogenic bacteria. Probiotics restore the microbiota bacterial balance and improve the immune function, as well as the gastrointestinal structure and function.⁵⁶

Bacterial translocation of probiotics has been reported anecdotally. Since the PROPATRIA trial,⁵⁷ which showed increased mortality among probiotic-treated pancreatitis patients due to gut ischemia, safety concerns have been expressed.

A meta-analysis of 13 RCTs did not demonstrate a reduction in the ventilation duration or lower ICU or hospital mortality rates. However, a reduced incidence of ICU-acquired pneumonia and ICU LOS was found.⁵⁸ In a recent Cochrane analysis, the effect on pneumonia was questioned due to the low-quality studies that were included.⁵⁹ Identification of which ICU patients could benefit from probiotics is unclear.

KEY POINTS

1. ICU admission lean body mass and cumulative protein and energy deficit are associated with outcome.
2. Admission nutritional assessment using the NUTRIC-score facilitates selection of patients who benefit from nutritional support.
3. Refeeding syndrome, as identified by hypophosphataemia after resuming nutrition, should lead to caloric restriction for 2 days and gradual introduction of calories.
4. Enteral feeding is preferred over parenteral nutrition and should be initiated early (24-48 hours after ICU admission) to preserve gut condition.
5. Absolute contraindications for enteral nutrition are intestinal obstruction, perforation, and ischemia.
6. Hemodynamic instability is only a temporary contraindication for enteral feeding; feeding can commence when stable vasopressor infusion is achieved.
7. In well-nourished patients with low NUTRIC-scores, trophic feeding is associated with similar outcomes as full nutritional support.
8. Measuring gastric residual volume reduces feeding efficiency; therefore it should be abandoned or high GRV up to 500ml/6 hours should be accepted.
9. Critical care nutrition protocols improve feeding adequacy.
10. Gastrointestinal symptoms such as diarrhea are common during an ICU stay; however, they are frequently due to other causes than enteral feeding.
11. There are no clear benefits of supplemental parenteral nutrition within 5 days of ICU admission.
12. Formulae to estimate energy expenditure are inaccurate; therefore indirect calorimetry is recommended.
13. Caloric overfeeding should be prevented; therefore nonnutritional calories from propofol, dextrose, and citrate infusion should be considered as an energy source.
14. Protein intake should be at least 1.2 gram/kg per day, with higher recommendations in patients with greater BMI and protein loss due to renal replacement therapy.
15. Based on contradictory results from clinical trials, pharmaconutrition with glutamine, arginine, and fish oil cannot be recommended.
16. Recommended daily allowances for vitamins and trace elements in critical illness are unknown; however, supplementation should be considered in patients on parenteral nutrition or enteral nutrition intake below 1500 kcal/day.
17. Although prebiotics and probiotics seem to be safe in most ICU patients, proven benefits in targeting gut microbiota with these strategies are lacking.

Clinical Pearls:

1. Clinical nutritional support must minimize tissue loss, optimize tissue repair, and minimize metabolic overloading.
2. Pushing nutritional intake beyond recommended levels may create additional metabolic stress.
3. Enteral nutrition support is generally considered the preferred route for nutrition, yet parenteral nutrition may be necessary to meet the need of critically ill children.

Nutritional support is a central therapy in the management of critically ill children. Patients of differing ages and conditions have fundamental differences in nutrient requirements and utilization. Our well-intended efforts to “increase” nutritional support may at times lead to greater harm than benefit through the provision of protein, carbohydrate, and fat far beyond what the critically ill child can utilize. In addition, metabolic complications such as total parenteral nutrition (TPN)-associated cholestasis, hepatic steatosis, and catheter-related infections are morbidities that have arisen with the advent of advanced nutritional support methods.

Recent reviews of the literature on nutritional support for critically ill children detail the lack of definitive studies to guide practice based upon scientific evidence.^{1,2} Therefore, many of the recommendations rest upon “good practice” principles based on expert consensus and the avoidance of known harm whenever possible. Those best practices are contained in the American Society of Parenteral and Enteral Nutrition (A.S.P.E.N.) guidelines for supporting children in the pediatric intensive care unit (PICU).³

Nutritional support has three primary goals. The first is the preservation of lean body mass to minimize the consequences of catabolism during critical illness. The second goal is the provision of suitable substrates to maintain or restore immune function and tissue repair. The third goal is the prevention of nutrition-related complications, including aspiration risks, in patients receiving enteral nutrition and the avoidance of nutrient-induced organ overload whether through excess carbohydrate (e.g., increased CO₂ production and hepatic steatosis) or excess protein/nitrogen load to the liver and kidney. This chapter provides the critical care clinician with a basic understanding of the issues necessary for providing effective and safe nutrition to critically ill children and those recovering from life-threatening illness.

IMPACT OF PHYSIOLOGIC STRESS IN CHILDREN

Life-threatening illness, sepsis, burns, trauma, and major surgical procedures elicit dramatic systemic inflammatory responses via activation of the immune system, clotting mechanisms, and the endothelium. The patient's ability to withstand the metabolic responses to such stresses and ultimately to reverse the process is central to recovery.⁴⁻⁶

The initial response to injury involves activation of endothelial and priming inflammatory cells such as neutrophils, macrophages, and lymphocytes. Such activation occurs through proinflammatory mediators, including tumor necrosis factor, interleukin-2, histamine, eicosanoids, heat-shock proteins, free radicals, platelet-activating factor, and tryptases.⁷ The same signals that activate the endothelium lead to vascular permeability changes and the activation of clotting mechanisms. Simultaneously, alterations in hepatic and peripheral protein metabolism occur, constituting acute phase changes.⁸ Proinflammatory

stimuli also play a role in regeneration and repair, and the timing of interventions is important.^{9,10} In response to injury, a range of neuro-humoral reactions occur, forming the classic “stress response,” which includes elevation of levels of growth hormone, endogenous catecholamines, glucagon, and cortisol. Gluconeogenesis occurs through the release of glycerol and gluconeogenic amino acids from the periphery, followed by their conversion to glucose in the liver and kidney. Hyperglycemia frequently is associated with this state and may induce glycosuria and an osmotic diuresis. Insulin activity is impaired at the tissue level, leading to so-called insulin resistance in the face of the powerful gluconeogenesis driven by stress hormones.

The breakdown of protein is a central theme in the body's response to stress. Hepatic uptake of amino acids increases for the conversion to glucose and the production of acute-phase proteins. Hepatic synthesis of other proteins, such as albumin and prealbumin, declines.¹¹ Urea-genesis increases, and nitrogen is liberated in the form of uric acid, creatinine, and urea. These catabolic changes account for the dramatic increase in nitrogen wasting seen during stress states. One of the major consequences of life-threatening physiologic stress is the net depletion of body protein representing the somatic protein pool (e.g., skeletal muscle mass) and functional tissues contained in the visceral protein pool (e.g., plasma proteins, enzyme systems, antibodies). With protein catabolism rates elevated by up to twofold, synthesis does not keep pace, and a state of negative nitrogen balance ensues.¹² In the resolution of the inflammatory response, the patient's immune system plays a central role in the recovery of wound healing and immune competence.¹³ The syndrome of multiple organ dysfunction seen in critically ill patients likely is due in part to the inability of the immune system to downregulate the inflammatory response to injury in specific organs. Additionally, acquired mitochondrial dysfunction leads to ineffective cellular energy production.¹⁴ Nutrition support of a critically ill patient is thought to be essential to achieve recovery, minimizing the subsequent period of convalescence.

The body's response to withholding feeding (i.e., starvation) in healthy individuals is qualitatively and quantitatively different from that seen when nutrient intake is absent during critical illness. In simple starvation, the body's regulatory mechanisms for sparing lean tissue and using triglycerides as the primary energy source are intact. Under the influence of the stress response, rapid depletion of lean tissues occurs, with the oxidation of amino acids, carbohydrates, and fats as energy substrates.

NUTRITION ASSESSMENT OF THE CRITICALLY ILL CHILD

Nutrition assessment of hospitalized children is a central part of the initial examination and evaluation. Undernutrition in developed countries is most frequently found in hospitalized children in the setting of chronic illness.¹⁵ In a multicenter study, over 30% of children admitted to the PICU had evidence of severe malnutrition.¹⁶ Conversely, an estimated 17% of children in the United States aged 2 to 19 years were identified as obese in 2011-2012.¹⁵ Yet obesity is not an indicator of nutritional adequacy, but excessive calorie intake is. Obese children may have access to calorically dense yet poor nutritional quality foods and can present with micronutrient deficiencies, including vitamin D, B₁₂, and iron.¹⁷⁻¹⁹ Excess body weight is often falsely interpreted as well

nourished, while we recognize that a 10% weight loss from baseline indicates severe acute malnutrition.¹⁵ The presence of preexisting severe malnutrition may complicate critical care management through the presence of marasmus cardiomyopathy, severe intracellular energy deficiency, and the development of refeeding disequilibrium when nutrients are provided in the PICU.²⁰⁻²² Skilled clinicians, including pediatric-trained registered dietitians/registered nutritionists (RD/RDN), must fully assess critically ill children for the presence of malnutrition to avoid known complications of refeeding.

The initial nutrition evaluation consists of assessing the patient's anthropometric measurements (weight, height, midarm circumference) and historical evidence for recent weight loss and nutrient intake.¹⁵ Nutrition history should include the presence and duration of nausea, vomiting or diarrhea, fever, frequent infections, fatigue, food aversion, abdominal discomfort, and feeding intolerance. The Centers for Disease Control (CDC) recommends that the World Health Organization (WHO) growth data charts be used to evaluate growth data in children 0-2 years of age and the CDC growth data charts used for children 2-20 years of age.^{23,24} Genetic and ethnic background should be taken into consideration. The presence of genetic syndromes (e.g., Down or Turner syndrome) and the child's birth status (e.g., prematurity, growth restricted) may also affect the child's growth, and disease-specific growth comparison data curves may help to establish the degree of variance from similar populations.

Clinicians caring for children who will experience more than a few days of hospitalization must be especially aware of the potential for acquired nutritional depletion. Potential sources of error exist in interpreting anthropometric measurements. Such errors are primarily related to changes in body water associated with acute critical illnesses in children, as in conditions producing capillary leak syndrome or defects in renal water clearance.

No nutrition-related serum biomarkers have been proven to identify malnutrition or predict clinical outcomes.²⁵ Frequently, serum proteins decrease during acute critical illness without reflecting preceding malnutrition. This phenomenon is seen frequently when capillary leak syndrome occurs in the first days following PICU admission in patients with sepsis, burns, surgical interventions, and ischemia-reperfusion injury. Through the loss of endothelial barrier function, large molecules such as albumin that are normally three to four times more concentrated in the vascular compartment than in the interstitial fluid, move into the extravascular space, lowering their concentration without a concomitant decrease in the total body pool of albumin. This effect may be very pronounced in patients who have received large volumes of crystalloid fluid during resuscitation. The synthesis of acute-phase proteins is increased, while the synthesis of albumin (half-life, ~20 days) and prealbumin (half-life, 2 days) is decreased.²⁶ These changes may be seen within 6 hours of the onset of severe physiologic stress. In infants followed after cardiac surgery, the return of CRP levels to less than 2 g/dL is associated with return to an anabolic state, with improving prealbumin levels.¹⁵ Such positive changes herald the impending return to a state of growth and tissue accretion.

Energy Expenditure

Nutritional support for critically ill children differs fundamentally from conventional nutrition for healthy children. Estimates of caloric and protein requirements during acute illness and recovery indicate that children have greater requirements for both calories and protein on a body weight basis when compared to critically ill adults. Yet, during periods of critical illness, the utilization of nutrients for growth is markedly inhibited by the hormonal response to stress and the circulating inflammatory mediators. Critically ill children may have a lower energy expenditure during mechanical ventilation and sedation because of their reduced movement and a transient absence of growth.¹⁵ In critically ill children, many investigators have found the resting energy expenditure (REE) to be less elevated than previously expected, leading to a risk of overfeeding.^{27,28} Thus, sedated, critically ill children with decreased activity levels can be at risk for overfeeding when using

standard age-appropriate equations for healthy children.²⁹ One of the most important points for clinicians prescribing nutritional support is to provide calories in a thoughtful manner based upon the available clinical guidelines and *avoid excess caloric intake* during the acute phase of illness.

Energy needs are determined using predictive equations or indirect calorimetry (IC). Although many predictive equations exist, their accuracy for determining energy requirements, particularly in critically ill children, is not clear.^{30,34} Predictive equations derived from healthy, nonhospitalized patients have been shown to overestimate the measured energy expenditure. Even equations developed for use in critically ill children fail to consistently predict REE when compared to measured energy expenditure using indirect calorimetry (IC).^{3,30} Because of the dynamic metabolic changes that occur during critical illness, the gold standard for determining energy metabolism is IC.³¹ Equations for estimating REE and TEE are summarized in Table 44-1.

Indirect calorimetry determines the resting energy expenditure (MREE) and respiratory quotients (RQ) by measuring whole-body oxygen consumption (VO_2) and the metabolic production of carbon dioxide (VCO_2).^{11,29,31} As in adult nutritional assessment, the *respiratory quotient* ($\text{RQ} = \text{VCO}_2/\text{VO}_2$) reflects substrate oxidation. The physiologic range for the RQ in humans is 0.67-1.2; any value much outside this range suggests an invalid study.³² RQ correlates with the percent calories provided/percent calories required, with mixed fuel use generally between 0.85 and 0.95; values greater than 1 indicate net fat synthesis.¹¹ Indirect calorimetry (IC) is well established in clinical nutrition but has been difficult to perform with consistent results in children. The lack of suitable equipment to perform IC in children has been a major obstacle to its widespread application.

Through indirect calorimetry, it has become clear that patients with similar clinical appearances may have widely differing metabolic rates when adjusted for age and weight.^{3,27,33-35} The differences may be as great as 300%, suggesting the potential for severe over- or under nutrition depending upon the values assumed.²⁸ Total energy expenditure (TEE) can vary depending on the route of nutrition delivery (enteral vs. parenteral), activity, progressive ventilation weaning, wound losses and intermittent pain and anxiety. Patients should be reassessed as their clinical status changes and adjustments are made to nutritional support. Most clinicians must rely upon information provided in published studies to guide the delivery of calories since most will not have a means of determining the REE by IC.³⁶

TABLE 44-1 Equations for Estimating Total Energy Expenditure (TEE) in Critical Illness

RESTING ENERGY EXPENDITURE (REE) Kcal/DAY

| | |
|-------------|---------------------------------------|
| 0-3 years | $61 \times \text{kg} - 54$ |
| 3-10 years | $23 \times \text{kg} + 500$ |
| 10-18 years | Male: $17.5 \times \text{kg} + 650$ |
| 10-18 years | Female: $12.2 \times \text{kg} + 745$ |

*Stress Factors:
Multiply REE by stress factors to estimate *total energy needs*:
Surgery: 1.1-1.5
Cardiac Failure: 1.2
Sepsis/Fevers: 1.2-1.6
Head Injury: 1.3
Trauma: 1.1-1.8
Burns: 1.5-2.5

REE adapted from World Health Organization. Energy and Protein Requirements. Report of a Joint FAO/WHO/UNU Expert Consultation. Technical Report Series 724. World Health Organization, Geneva, 1985.

Stress factors adapted from The ASPEN Pediatric Nutrition Support Core Curriculum 2010.

*Critically ill patients who are sedated, with minimal movements, and receiving ventilation support may have energy needs very close to the calculated REE. Multiplying by stress factor may exceed metabolic needs.

Protein

The high rate of protein turnover during critical illness is associated with an increase in ureagenesis and urinary nitrogen loss, which may amount to as much as 1-2 g/kg/day of protein equivalent. To minimize nitrogen loss, proteins or amino acids must be administered in amounts sufficient to replace losses, with additional protein to synthesize new tissue. Table 44-2 provides guidelines for the administration of protein to children in the PICU during different phases of illness. Nitrogen balance in response to nutrition support represents a continuum. In one study, the authors found that nitrogen balance was obtained at an intake of 2.8 g/kg/day.³⁷ Positive nitrogen balance was only achieved with amino acid infusion rates at the upper end of those typically used by clinicians. Of equal importance is the provision of calories in sufficient quantity to assure that protein can be used for synthesis rather than oxidized as an energy substrate.

In disease states with altered nitrogen clearance—for example, hepatic and renal failure—a decrease in protein support may be necessary to avoid excessive ammonia production and/or urea formation. Only in the rare incidence of hepatic encephalopathy should protein be limited, although severe protein restriction may impair hepatocyte regeneration and exacerbate malnutrition. With renal failure, urea clearance will increase dramatically once dialysis is initiated, allowing better nutrition to be provided. However, amino acid losses across the dialysis membrane can be substantial.³⁸

Fluids

Maintenance fluids for most patients can be estimated by conventional formulas based on body weight as follows. For each kilogram body weight from 0-10 kg, provide 100 mL/kg/day. For each kilogram body weight from 10-20 kg, add 50 mL/kg/day. For each additional kilogram of body weight over 20 kg, add 20 mL/kg/day. Thus, for a 25-kg child, maintenance daily fluid is 1600 mL/day $([10 \text{ kg} \times 100 \text{ mL/kg/day}] + [10 \text{ kg} \times 50 \text{ mL/kg/day}] + [5 \text{ kg} \times 20 \text{ mL/kg/day}])$.³⁹ Fluid needs increase with fever or persistent tachypnea due to increased insensible fluid losses. Additional fluids must be provided when abnormal losses are present as with diarrhea, nasogastric drainage, or from wound loss in burns or from other sites. The replacement fluid composition is based on the content of sodium, potassium, bicarbonate, and chloride lost and conforms to conventional surgical and medical guidelines for fluid replacement. Typically, maintenance fluids should provide sodium (3-5 mEq/kg/day) and potassium (2-3 mEq/kg/day) salts as well as a modest amount of glucose (5% or 10% if <6 months of age).

TABLE 44-2 Guidelines for Protein Support in Critically Ill Children

| PROTEIN: g/kg/DAY | | | |
|-----------------------|------------------|-------------------------------|--|
| AGE | RDA ^a | CRITICAL ILLNESS ^b | RENAL DISEASE* (PREDIALYSIS-DIALYSIS) ^c |
| 0-6 months | 1.52 | 3 | 1.5-2.1 |
| 7-12 months | 1.2 | 2-3 | 1.7-1.7 |
| 1-3 years | 1.05 | 2 | 1.05-1.5 |
| 4-13 years | 0.95 | 1.5-2 | 0.95-1.35 |
| Greater than 14 years | 0.85 | 1.5 | 0.85-1.2 |

^cNational Kidney Foundation. KDOQI Clinical Practice Guideline for Nutrition in Children with CKD: 2008 Update. Am J Kidney Dis 2009;53(Suppl. 2):S1-S124.

*Protein needs in critical illness are elevated; thus patients with renal dysfunction may require greater protein provision than non-critically ill children with renal disease.

Recent trends in providing electrolytes has favored a *balanced* electrolyte solution containing acetate salts of 1-2 mEq/kg/day to minimize the development of hyperchloremia caused by the large chloride load contained in fluids and medications. The provision of glucose in maintenance fluids is intended to spare lean tissue and prevent hypoglycemia, especially in infants with low glycogen stores.

NUTRITION SUPPORT RECOMMENDATIONS FOR THE CRITICALLY ILL CHILD

Enteral Nutrition Support

The decision to provide nutrition via a parenteral or enteral route depends upon the anticipated time to resumption of normal dietary intake, the available routes of nutrient administration, underlying metabolic or endocrine conditions, and the existence of organ dysfunction. In all critically ill patients with a functioning gastrointestinal tract, enteral nutrition is the preferred mode of nutrition support.³ Table 44-3 reviews the indications and contraindications for enteral feedings. Enteral nutrition is associated with lower rates of nosocomial infections and reduced mortality.¹¹ Enteral nutrition is thought to support intestinal integrity and the intestinal microbiome.³⁹ In addition, the avoidance of central venous access reduces the risk of central line-associated infections.

Early enteral nutrition, *even at low volumes*, can support intestinal function, reduce hepatic cholestasis, and reduce infection rates.⁴⁰ Gastric feedings are generally preferred in preterm infants, even during periods of critical respiratory illness.^{3,41} In the PICU, concerns for gastric reflux and aspiration of gastric contents favor postpyloric enteral feeding to reduce aspiration risk.³ Transpyloric feeding tubes can be placed at bedside by experienced clinicians⁴² or under fluoroscopic guidance. Metoclopramide or erythromycin can facilitate placement of a transpyloric tube when gastric motility is impaired. Even when a transpyloric feeding tube cannot be placed, continuous enteral feeding via a nasogastric tube may confer most of the benefits.⁴⁴

During critical illness, continuous drip feedings may be better tolerated than bolus feedings, especially in patients with significant respiratory distress and/or hypoactive bowel function. Continuous feeding is always required with postpyloric tube placements. Breast milk is the optimal nutrient source for critically ill infants and can be delivered by feeding tube. Specialized supplements can be added to breast milk to increase the nutrient density to better meet the needs of critically ill infants. Modern enteral nutrition formulas for critically ill children are lactose free, may contain medium-chain triglycerides, and contain ample proteins to meet their increased needs. Adult formulas may be appropriate in critically ill children greater than 10 years of age. A variety of formulas exist, and the availability may vary from country to country. The hospital dietitian is best prepared to help select the most suitable formula.

Infusion rates are typically begun conservatively at ~1 mL/kg/hr, with a stepwise increase every 4 to 6 hours as tolerated up to the desired final rate. Clinicians must maintain vigilance for evidence of feeding intolerance. In patients with altered tissue perfusion, enteral feedings may be feasible, yet caution should be exercised in patients requiring high doses of vasopressors.⁴⁰ Any signs of marked abdominal distention, profuse diarrhea, emesis, or the development of a new metabolic acidemia may indicate the need to hold enteral feedings and assess the abdomen before reinstituting feeds.⁴⁴

Parenteral Nutrition

One of the great achievements of clinical nutrition science has been the development of safe and effective nutrient support by the intravenous route. Parenteral nutrition (PN) has been invaluable in the survival of premature infants, children with congenital or acquired bowel defects, and those who do not tolerate enteral nutrition due to

TABLE 44-3 Indications and Contraindications for Enteral Feeds in Critical Illness

| INDICATIONS (TIMING OF INSTITUTING FEEDS) | CONTRAINDICATIONS | RELATIVE CONTRAINDICATIONS |
|---|--|--|
| INABILITY TO CONSUME ADEQUATE ORAL NUTRITION WITHIN AN ACCEPTABLE TIME FOR AGE AND NUTRITIONAL STATUS Malnutrition on Admission <ul style="list-style-type: none"> 0-2 years: <3 days 3-10 years: 3-5 days >10 years: 5-7 days Well Nourished on Admission <ul style="list-style-type: none"> 0-2 years: 3 days 3-10 years: 5 days >10 years: 7 days Hypermetabolic Condition <ul style="list-style-type: none"> Cyanotic heart disease Severe trauma Sepsis/SIRS ARDS Thermal injury Inability to Take Oral Nutrition <ul style="list-style-type: none"> Oral/laryngeal/esophageal carcinomas Congenital malformations Neurologic disorders | DYSFUNCTIONAL GASTROINTESTINAL TRACT <ul style="list-style-type: none"> Severe ileus High output intestinal fistulas Severe necrotizing pancreatitis Intestinal ischemic injury Intractable emesis Severe secretory diarrhea SPECIAL CIRCUMSTANCES <ul style="list-style-type: none"> Expressed desires of family for no artificial nutrition End-stage disease or terminal illness wherein supportive therapies are discontinued and nutrition will not contribute to comfort measures. | CONDITIONS IN WHICH ENTERAL FEEDING TUBES MAY RISK SECONDARY INJURY <ul style="list-style-type: none"> Neutropenia patients without established enteral access Facial and/or neck trauma (unable to place enteral feeding tubes) CONDITIONS THAT MAY LIMIT TOLERANCE BUT THAT ARE NOT ABSOLUTE CONTRAINDICATIONS TO ENTERAL FEEDS <ul style="list-style-type: none"> Short bowel syndrome Intestinal fistulas <ul style="list-style-type: none"> May attempt enteral feeding if fistula is in distal bowel (ileum or colon) May attempt with fistulas in the proximal bowel with enteral access distal to the fistula Feeds should be discontinued if fistula output becomes excessive with the initiation of feeds. |

Data from Enteral Nutrition in Adult and Pediatric Patients. JPEN J Parenter Enteral Nutr. 2002;26:1:13A-138SA.

malabsorption, surgery, or other causes of bowel dysfunction. PN should be considered in any patients who cannot tolerate enteral feedings. However, PN may come with a significant morbidity in terms of iatrogenic electrolyte and acid-base disturbance, cholestasis, hepatic fibrosis following prolonged use, and increased risk of bacterial and fungal infections. The goals of PN support during critical illness need to be clarified and kept realistic to avoid adding unnecessary metabolic stress to already compromised pulmonary, renal, and hepatic function. The timing for institution of PN intervention should be carefully considered and corresponds to those given under enteral nutrition indications in Table 44-3. Excess PN may contribute to organ dysfunction and should be avoided: *More than recommended is not better for these patients.*

Parenteral nutrition is composed of dextrose, amino acid solutions, electrolyte salts and minerals, added vitamins and trace elements, and sterile water. Some PN pharmacies will add lipids to the mixture as a 3-in-1 solution, or they may be delivered as separate infusions. Due to the high osmotic content and risk of extravasation injury, *peripheral* parenteral nutrition solutions are not recommended to exceed 900 mOsm/L, which limits *peripheral* solutions to dextrose 12.5 g/100 mL and amino acids 2 g/100 mL.⁴³ Central venous access will allow for more concentrated solutions, typically up to 25 g/100 mL dextrose and 5 g/100 mL amino acids. Parenteral nutrition solutions may not be compatible with some intravenous medications. Consulting a pediatric pharmacist regarding compatibility is prudent.

Glucose is the primary energy source for the brain, erythrocytes, and renal medulla. Infants and malnourished children have lower glycogen body content and may develop hypoglycemia during periods of fasting. Most PICU protocols include intravenous fluids with low-dose dextrose (5-10 g/100 mL) to reduce catabolic losses and support essential glucose needs in critical illness. Once parenteral nutrition is initiated, the cellular energy requirements of most critically ill children can be met, and euglycemia can be maintained through the infusion of 5-8 mg/kg/min of dextrose. This range represents ~25-40 kcal/kg/day of carbohydrate calories and is a close first approximation of the *basal* cellular energy expenditure seen in many hospitalized children. Glucose infusion rates less than 2 mg/kg/min may lead to hypoglycemia or starvation ketosis. When infusion rates exceed 10-12 mg/kg/min of glucose, net lipogenesis and hyperinsulinemia may ensue

which can further complicate clinical management.⁴³ While an occasional patient may become acutely hyperglycemic or experience dramatic electrolyte changes following the initiation of PN, most patients will tolerate it well and can be advanced to full PN within a few days. Insulin is used as needed to achieve acceptable glucose levels, generally <240 mg/dL. Close glucose monitoring during insulin infusion is required to avoid episodes of hypoglycemia.

Specific amino acid solutions developed for neonates contain taurine, tyrosine, cysteine, and histidine, which are advantageous for select newborns and young infants with biliary disease, sepsis, or under high physiologic stress. These solutions contain increased branched-chain amino acids that are conditionally “essential-for-age” in infants and decreased amounts of nonessential amino acids. In premature infants or those on prolonged PN, intravenous carnitine supplementation has been advocated to aid in triglyceride clearance through enhanced β -oxidation of fatty acids.⁴⁵ In older children, conventional amino acid solutions designed for adult patients provide adequate dietary nitrogen.

Critically ill children have a high rate of fat oxidation; thus, fatty acids are a prime source of energy in metabolically stressed children.³ Intravenous lipid emulsions were originally developed to prevent essential fatty acid deficiency, which can arise in a matter of days in critically ill children.³ Provision of only 4% to 5% of total calories as essential fatty acids containing fat emulsions will prevent essential fatty acid deficiency.³ Calories from fat should not exceed 20% to 30%, with a maximum of 2-4 g/kg/day of intravenous lipids. A 20% lipid emulsion is the preferred source of intravenous fat and provides 2 kcal/mL. For pediatric patients, lipid emulsions are administered continuously unless rising plasma triglyceride levels suggest inadequate clearance. This condition may be seen during sepsis, with increased generation of triglycerides from high carbohydrate infusion and increased peripheral lipolysis. Recent research suggests that the current lipid products, derived primarily from soy oils, may increase inflammation and contribute to parenteral nutrition-associated liver disease.⁴⁶ Current research indicates the combined use of olive and fish oils may produce less associated inflammation; however, these products are not currently approved for use in the United States. Table 44-4 presents the accepted guidelines for prescribing PN and for determining the glucose infusion rate (GIR) and advancement of PN support based on weight.

TABLE 44-4 General Guidelines for Dosing Pediatric Parenteral Nutrition

| | MINIMUM DOSE | ADVANCE BY | MAXIMUM DOSE | CALORIES/kg/DAY |
|------------------------|--|--|---|---|
| Dextrose | 7-10 g/kg/d (GIR 5-7) Typically 10 g/100 mL | Add +2-4 g/kg/d (+GIR 1-3) Add + 2.5-5 g/100 mL | 14-17 g/kg/d (GIR 8-12) 15-25 g/100 mL | 3.4 kcal/g 27-41 kcal/kg/day |
| Amino acids | 1-2 g/kg/d Typically 2 g/100 mL | 0.5-1 g/kg/d Add + 0.5-1 g/100 mL | 2-4 g/kg/d 2-5 g/100 mL | 4 kcal/g 8-20 kcal/kg/day |
| Lipids 20% solution | 0.5-1 g/kg/d = 2.5-5 mL/kg/d | +0.5-1 g/kg/d = +5 mL/kg/d | 0.5-3 g/kg/d = 2.5-15 mL/kg/d | 10 kcal/g (2 kcal/mL) 5-30 kcal/kg/day |

Calculate glucose infusion rate (GIR):

Dextrose g/100 mL \times volume (mL/kg/day) \div 1.44 = mg/kg/min

(1.44 = 1440 mL/day \div 1000 mg/g dextrose)

SHOULD NUTRITION SUPPORT BE PROTOCOL DRIVEN?

Multicenter studies suggest that frequent interruptions in nutrition support can significantly impair nutrition delivery. However, patients who received a higher percentage of their prescribed enteral nutrition experienced an improved 60-day survival.¹⁶ Research indicates that feeding protocols may enhance the delivery of nutrition, decrease the use of PN, increase tolerance of enteral nutrition, and shorten the time to reach goal nutrition.^{44,47} The recommendations are for early institution of enteral feeding via NG or transpyloric route, planned rate of advancing feedings (e.g., every 4 hours, if tolerated), and the caloric goal. However, a recently published multicenter trial suggests that early PN increased morbidity from infection compared to starting 1 week after admission (18% early vs. 10% late), although mortality was no different between the early and late groups.⁴⁸ Thus, early PN may carry risks with little proven benefit.

SUMMARY

Nutritional support of critically ill children is a central part of intensive care medicine. The complexity of pediatric disease and the wide range

of ages and body conditions, as well as the multiple options for nutrient delivery necessitate close collaboration between physicians and pediatric dietitians who are familiar with children's nutrition requirements during critical illness. Although PN support has associated risks, it can offer lifesaving treatment to patients with dysfunctional gastrointestinal tracts. Enteral nutrition continues to be the preferred route of nutrition whenever possible, even in small amounts, as it offers multiple clinical benefits during critical illness.

KEY POINTS

1. Increasing nutritional intake beyond recommended levels may create additional metabolic stress.
2. A significant degree of benefit from nutrition will be seen by simply avoiding starvation through the provision of a portion of the estimated nutritional needs by enteral or parenteral route.
3. Clinical nutritional support must minimize tissue loss, optimize tissue repair, and minimize metabolic overloading.

Bed rest has historically been prescribed as an adjunct to the treatment of acute illness and rehabilitation after surgery. Even as physicians and researchers began to realize the “evil sequelae of complete bed rest”²¹ in both medical and surgical patients, the therapy remained commonplace in the intensive care unit (ICU). Indeed, healthcare providers in the ICU have traditionally focused their attention on normalizing the physiologic derangements that threaten their patients’ survival. However, therapeutic advances and improvements in the management of critically ill patients have improved the outcomes in this patient population.²⁻⁴ As survival from critical illness has improved, the long-term complications and associated therapies have become more apparent. A large proportion of these patients experience long-term cognitive, psychological, and physical disability, with less than half of critical illness survivors returning to work 1 year after ICU discharge.⁵⁻⁸ Early mobilization and ambulation of critically ill patients are feasible, safe, and effective interventions that result in improvements in physical functional and neuropsychiatric outcomes.⁹⁻¹⁵

■ THE PHYSIOLOGY OF BED REST

Bed rest has, at one time or another, been promoted as a therapy for almost all ailments. Hippocrates suggested that all pain could be relieved by bed rest.¹⁶ However, as early as the 1940s, it was recommended that “the physician ... always consider complete bed rest as a highly unphysiological and hazardous form of therapy.”²¹ Nonetheless, it was not until recently that the medical community began to acknowledge the ill effects of complete inactivity and immobility during critical illness.

Inactivity and immobility have profound effects on skeletal muscle. Disuse leads to reduced protein synthesis, accelerated proteolysis, and increased apoptosis, ultimately resulting in a catabolic state, atrophy, and clinical weakness.^{17,18} In a study of young, healthy volunteers, 28 days of bed rest resulted in a 0.4 ± 0.1 -kg loss of lean leg mass and a $22.9 \pm 3.5\%$ reduction in leg extension strength.¹⁹ When healthy volunteers were subjected to 28 days of bed rest and hydrocortisone to achieve plasma cortisol levels mimicking trauma or critical illness, leg extension strength decreased even further ($28.4 \pm 4.4\%$, $P = 0.012$), and the loss of lean leg mass was increased threefold compared to bed rest alone (1.4 ± 0.1 kg, $P = 0.004$).²⁰ Therefore, it is apparent that both immobility and the hormonal effects of critical illness contribute to increased weakness in ICU patients.

■ NEUROMUSCULAR WEAKNESS IN THE ICU

Neuromuscular weakness is a common complication of critical illness. Approximately half of ICU patients with sepsis, multiorgan failure, or prolonged mechanical ventilation have electrophysiologic evidence of neuromuscular dysfunction.²¹ In patients with both sepsis and multiorgan failure, the incidence can be as high as 100%.²² Electrophysiologic weakness is evident as early as 18-24 hours into the onset of a critical illness.^{22,23} Clinical evidence of weakness is evident in a smaller but significant portion of ICU patients.²⁴

The differential diagnosis of neuromuscular weakness in the ICU is long and includes critical illness neuromyopathy, an umbrella term that includes critical illness neuropathy, critical illness myopathy, and neuromuscular junction disorders. ICU-acquired weakness (ICUAW) is defined as bilateral symmetric limb weakness and is the clinical manifestation of critical illness neuromyopathy. It typically presents as flaccid quadriplegia with hyporeflexia or areflexia, although the cranial nerves are usually spared.²⁵ This weakness increases the duration of mechanical ventilation, prolongs ICU and hospital length of stay (LOS), and increases mortality.^{21,26}

A number of risk factors have been implicated in the development of ICUAW. These include the systemic inflammatory response syndrome, sepsis, multiorgan failure, renal replacement therapy, catecholamine administration, and hyperglycemia.²¹ The relationship between ICUAW and other factors, such as age, gender, corticosteroids, or neuromuscular blocking agents is inconsistent.^{4,21,24,27-29} Unfortunately, there have been few investigations of interventions to prevent ICUAW. With ill-defined or unmodifiable risk factors and a lack of preventive measures, ICUAW has become common in survivors of critical illness and has serious long-term consequences. Indeed, survivors of the acute respiratory distress syndrome report poor functional status at 1-year post discharge despite the normalization of pulmonary function tests. Secondary to muscle loss, weakness, and fatigue, only 49% of these patients were able to return to work within 1 year of their critical illness.⁷ Five years after ICU discharge, 100% of survivors reported subjective weakness and decreased exercise capacity compared to before ICU admission.⁸ Similarly, survivors of severe sepsis with no functional limitations prior to ICU admission developed significant limitations in their ability to perform activities of daily living and continued to develop functional limitations at a more rapid rate following hospital discharge.⁵ Early mobilization and ambulation have been suggested as one possible intervention to prevent the weakness and functional decline associated with critical illness.

■ EARLY MOBILIZATION AND AMBULATION IN THE ICU

Safety and Feasibility

Multiple studies have confirmed the safety and feasibility of physical therapy in the medical ICU population.^{9,10,12,30,31} Morris et al. performed a prospective cohort study of 330 patients in a university-based medical ICU and showed that an ICU mobility team was able to initiate an early mobilization protocol within 48 hours of mechanical ventilation, without observing any adverse events or accruing increased cost.³⁰ Similarly, in a study by Pohlman et al., patients were successfully mobilized as early as one day after the initiation of mechanical ventilation.⁹ Physical therapy was successfully provided to 90% of medical ICU days during mechanical ventilation, despite a potential barrier to mobilization (e.g., acute lung injury, administration of vasoactive medications, delirium, renal replacement therapy, or obesity) present in 89% of the sessions. Minor adverse events, such as oxygen desaturation, increased heart rate, agitation, or ventilator dyssynchrony, occurred in 16% of sessions but required cessation in only 4%. No

unplanned extubations occurred. More recently, a prospective observational study of 1110 medical ICU patients, in which 5267 physical therapy sessions were conducted on 4580 patient days, revealed a physiologic abnormality or potential safety event in only 0.6% of sessions.¹² Only 4 (0.1%) of these occurrences required additional treatment or increased cost, and LOS was not increased. Furthermore, ICU rehabilitation programs aimed at reducing the time from ICU admission to physical therapy are sustainable in the long term. A recent study evaluating the effect of an ICU rehabilitation program in a medical ICU showed a sustained decrease in time to mobilization over a 5-year period.³²

Few studies have evaluated the safety and feasibility of early mobilization and ambulation in surgical ICU patients, where issues, such as wound healing, fractures, weight-bearing limitations, incisional pain, must be considered. A prospective observational study of early mobilization in a surgical ICU showed that early mobilization can occur safely as early as ICU day 1, without significant adverse events.³³ In a retrospective study of early mobilization in a trauma and burn ICU, Clark et al. reported no adverse events with physical therapy.³⁴ A subsequent review of the evidence for early mobilization in critically ill trauma patients concluded that there is a lack of evidence in this population but outlined injury-specific guidelines.³⁴ Early mobility also appears to be safe in the neuro intensive care unit (neuro-ICU) population. Indeed the implementation of a comprehensive mobility initiative in a neuro-ICU resulted in a 300% increase in mobility among patients, with no significant adverse events, such as falls or inadvertent line disconnections.³⁵ Furthermore, case reports suggest that even patients with left ventricular assist devices³⁶ and those on extracorporeal membrane oxygenation³⁷⁻⁴⁰ can safely participate in physical therapy programs. At our institution, we routinely ambulate patients on extracorporeal membrane oxygenation and extracorporeal life support systems.

Importantly, one commonly cited barrier to early mobilization and ambulation is the femoral catheter, which has recently been shown to be safe in the setting of physical rehabilitation. Indeed, in a cohort of 239 patients with femoral venous, arterial, or hemodialysis catheters, 101 patients received physical therapy interventions for a total of 253 sessions over 210 ICU days.⁴¹ The highest daily activity level was standing or walking, which occurred on 23% of days, and no adverse events were reported. However, of note, only 6 (6%) of patients had femoral hemodialysis catheters and none of these patients achieved a level of standing or walking. Another cohort of 77 patients with 92 femoral catheters underwent a total of 210 physical therapy sessions with 630 mobility activities and similarly found no adverse events. However, ambulation accounted for less than 10% of mobility activities, and it is unclear if any patients with hemodialysis catheters stood or walked.⁴² Therefore, femoral catheters need not be viewed as a barrier to mobilization, but caution must be taken with femoral hemodialysis catheters until there is more convincing evidence of safety.

Outcomes

The strongest evidence to support the benefit of early mobilization and ambulation can be obtained from two randomized controlled trials. Burtin et al. randomized 90 medical and surgical ICU patients on ICU day 5 to bedside ergometry with standard treatment, including respiratory physiotherapy and active motion sessions of the upper and lower limbs compared to standard treatment alone.⁴³ At hospital discharge, a 6-minute walking distance and the subjective feeling of well-being were significantly higher in the treatment group. Schweickert et al. randomized 104 medical ICU patients who had been on mechanical ventilation for less than 72 hours, to either daily sedation interruption and early exercise/mobilization or daily sedation interruption with therapy as ordered by the primary medical team.¹³ Patients in the intervention group had less delirium, more ventilator-free days, and an increased return to independent functional status at the time of hospital discharge.

Observational studies have also shown that early mobilization and ambulation are associated with decreased ICU and hospital LOS,^{30,44,45} as well as decreased delirium⁴⁵ without an increase in cost.³⁰ Early mobilization and ambulation can even lead to cost savings.⁴⁶ In the trauma and burn population, early mobilization and ambulation have been associated with decreased airway, pulmonary, and vascular complications, including ventilator-associated pneumonia and deep vein thrombosis.³⁴ In the neurosurgical ICU, increased mobility resulted in decreased restraint use, infections (including ventilator-associated pneumonia), decreased ICU, and hospital LOS.³⁵ Several specialty societies now recommend aggressive rehabilitation in the critically ill.^{47,48}

IMPLEMENTATION AND MONITORING

Implementation of an early mobilization and ambulation program is an iterative process that requires a structured approach, transdisciplinary team, collaborative environment, and support from administration and senior management. The use of a vetted framework, such as the Plan-Do-Study-Act (PDSA) model, the six sigma model,⁴⁹ or the 4-step model for large-scale knowledge translation suggested by Pro-novost et al.⁵⁰ increases the likelihood of success and sustainability of an intervention.

Planning and Engaging Phase

The first stage begins with summarizing and publicizing the evidence for early mobilization, including its safety, feasibility, sustainability, and effectiveness. Next, an interdisciplinary team, including physicians, nurses, physical therapists, respiratory therapists, senior executives, and other stakeholders, should be created. This team works with the frontline staff to navigate the early mobilization process and ensure a supportive and collaborative culture within the unit. Culture is of utmost importance, as “unnecessary immobilization” has been shown to occur frequently in ICUs where early mobilization is not ingrained in the culture.⁵¹ The team should then create a protocol for early mobilization, explicitly defining inclusion and exclusion criteria with the goal of capturing as many patients as possible and avoiding unnecessary exclusions. Of course, clinicians should consider each patient’s baseline, current clinical status, and clinical trajectory within the context of the prespecified criteria. Fig. 45-1 provides a sample algorithm for the delivery of physical therapy in critically ill patients.⁴⁵ Note that the type of physical activity performed depends on the status of the individual patient. Various methods of physical activity have been used successfully in the ICU, including traditional activities, such as sitting on the edge of the bed, standing, sitting in a chair, and ambulating. However, other activities, such as cycle ergometry⁴³ and even video games,⁵² are also safe and feasible. Careful consideration of certain populations (e.g., trauma patients, neurosurgical patients, patients with open abdominal wounds) should be given⁵³ and may require consultation with specialty services to delineate the appropriate activity level for these patients. Additionally, the team should consider whether early mobilization will be implemented on its own or as a part of a larger bundle of care processes. This includes the awakening and breathing, coordination, delirium monitoring and management, as well as early exercise and mobility (ABCDE) bundle^{11,53} or the ABCDEF bundle, which also encompasses family engagement.⁵⁴

Once a preliminary protocol has been identified, a sample patient can be used to assess workflow and potential barriers. Potential barriers should be discussed with all stakeholders, as perceived barriers may differ among disciplines. Table 45-1 describes a number of potential barriers to early mobilization and ambulation in addition to associated solutions.^{45,55} Note that these barriers include not only patient-related variables (e.g., the presence of lines, tubes, and drains) but also organizational, cultural, and environmental barriers. The latter include the lack of appropriate equipment (e.g., portable monitors and ventilators) and default bed rest orders. Cost is also a commonly perceived barrier,

TABLE 45-1 Potential Barriers to Early Mobilization and Suggested Solutions

| BARRIER | SOLUTION |
|--|---|
| Endotracheal tubes, central venous catheters, other lines and drains | Secure device Train staff in best practices |
| Hemodynamic derangements | Educate staff on evidence of safety Provide specific exclusion guidelines |
| Sedation | Integrate daily sedation holiday into PT/OT protocol Encourage sedative administration on as-needed basis instead of continuous infusion Use validated sedation scoring system to evaluate sedative needs |
| Delirium | Normalize sleep-wake cycle Expose patient to sunlight during daytime hours Redirect patient frequently Minimize benzodiazepines and narcotics Monitor for delirium with validated scoring system |
| Inappropriate equipment | Purchase necessary equipment (portable monitors, portable ventilators) Consider options for bedside or in-room PT/OT if equipment purchase is not feasible |
| Insufficient staffing | Hire additional personnel Reorganize staff (example: shifting one nurse from night to day shift since PT/OT more likely to occur during the day) Train and utilize nursing students and PT students taking ICU elective Implement technologic solutions to maximize staff efficiency |
| Lack of physician referrals for physical therapy | Streamline physical therapy orders Use computerized order entry Make default activity order “ad lib” Perform joint PT/nursing/ICU team rounds to identify patients appropriate for mobilization Implement automatic referral to PT/OT |
| Fear of intervention/cultural roadblock | Create ongoing dialogue to address stakeholder concerns Educate staff on safety and benefits of intervention Incorporate early mobilization into ICU culture |
| Lack of leadership | Recruit transdisciplinary team Identify physician champion Include senior management/hospital administrators |

Data from Lipshutz et al.⁵⁵ and Engel et al.⁴⁵ ICU, intensive care unit; OT, occupational therapy; PT, physical therapy.

particularly among hospital administrators, despite evidence that early mobilization can be implemented with no additional cost and may be cost saving.⁴⁶

The planning and engaging phase also includes the development of a measurement plan and specification metrics used to evaluate the program. These can be either process or outcome measures. Process measures include the percent of patients being referred to physical therapy, the number of physical therapy sessions occurring per ICU day, and the time from ICU admission to ambulation. Possible outcome measures include the highest activity level achieved, incidence or duration of delirium, functional status at the time of ICU discharge, ICU or hospital LOS, cost, patient and family satisfaction, hospital discharge destination, and mortality. The metrics chosen should be easily measured and reproducible. Ideally, data should be collected both before and after implementation of the program to ensure that a pre-post analysis can be performed. Adverse events should also be defined and recorded to ensure that the program is safe for patients, family, and staff.

Executing Phase

Pilot testing the program in a subset of ICU beds may be prudent to help identify issues and optimize the protocol prior to dissemination

to all critically ill patients. Unit-based marketing campaigns advertising and supporting the initiative should precede the initial rollout to alert providers and remind staff of the benefits of physical therapy in the ICU. Members of the interdisciplinary team should be readily available to encourage and support frontline providers, answer questions, and quell anxieties associated with ambulating critically ill patients. Additionally, team members should continuously request feedback on the implementation process and the algorithm in use. In addition, they should also attempt to identify barriers not previously recognized, with the goal of making changes rapidly to address concerns and improve the program. Early achievements should be applauded and celebrated, with staff, patients, and families acknowledged for their efforts.

Evaluating and Improving Phase

The evaluation phase continues indefinitely. Evaluation can be both qualitative (e.g., in the form of informal interviews, focus groups, and surveys) or quantitative. The quantitative assessment is composed of the metrics previously defined in the planning phase. One feasible and reliable way to evaluate the success of an early mobilization and ambulation program is to use an ICU mobility scale. Hodgson et al. recently developed and validated an 11-point mobility scale.⁵⁶ This scale

TABLE 45-2 ICU Mobility Scale

| CLASSIFICATION | DEFINITION |
|---|---|
| 0 Nothing (lying in bed) | Passively rolled or passively exercised by staff, but not actively moving |
| 1 Sitting in bed, exercises in bed | Any activity in bed, including rolling, bridging, active exercises, cycle ergometry, and active assisted exercises; not moving out of bed or over the edge of the bed |
| 2 Passively moved to chair (no standing) | Hoist, passive lift, or slide transfer to the chair, with no standing or sitting on the edge of the bed |
| 3 Sitting on edge of bed | May be assisted by staff, but involves actively sitting on the side of the bed with some trunk control |
| 4 Standing | Weight bearing through the feet in the standing position, with or without assistance. This may include use of a standing lifter device or tilt table |
| 5 Transferring bed to chair | Able to step or shuffle through standing to the chair. This involves actively transferring weight from one leg to another to move to the chair. If the patient has been stood with the assistance of a medical device, they must step to the chair (not included if the patient is wheeled in a standing lifter device) |
| 6 Marching on spot (at bedside) | Able to walk on the spot by lifting alternate feet (must be able to step at least 4 times, twice on each foot), with or without assistance |
| 7 Walking with assistance of 2 or more people | Walking away from the bed/chair by at least 5 m (5 yards) assisted by 2 or more people |
| 8 Walking with assistance of 1 person | Walking away from the bed/chair by at least 5 m (5 yards) assisted by 1 person |
| 9 Walking independently with a gait aid | Walking away from the bed/chair by at least 5 m (5 yards) assisted by a gait aid, but no assistance from another person. In a wheelchair-bound person, this activity level includes wheeling the chair independently 5 m (5 yards) away from the bed/chair |
| 10 Walking independently without a gait aid | Walking away from the bed/chair by at least 5 m (5 yards) without a gait aid or assistance from another person |

Reprinted with permission from Hodgson et al. and Heart & Lung/Elsevier (page 21, Fig. 45-1).⁵⁶

(Table 45-2) describes the highest level of activity achieved by a patient on a given day, ranging from a score of 0, which indicates no activity (patient lying in bed), to 10, which indicates being able to walk independently without an assistance device. In a study of 100 medical, surgical, and trauma ICU patients, the scale was a feasible tool with high interrater reliability among nurses and physical therapists of various levels. Other important metrics include the incidence of

delirium, ICU and hospital LOS, hospital discharge destination (i.e., home versus rehabilitation facility or skilled nursing facility), and the incidence of adverse events. Ongoing improvement should take place in response to issues, staff concerns, or poorly performing metrics. Metrics that improve initially and then show a decrement indicate a problem with sustainability and should trigger an in-depth review of the program and re-engagement of the frontline staff.

KEY POINTS

1. A large proportion of survivors of critical illnesses experience long-term cognitive, psychological, and physical disability, with less than half of survivors returning to work by 1 year after ICU discharge.
2. Prolonged periods of inactivity and immobility lead to reduced protein synthesis, accelerated proteolysis, and increased apoptosis. This ultimately results in a catabolic state, atrophy, and clinical weakness.
3. Early mobilization and ambulation have been suggested as possible interventions to prevent the weakness and functional decline associated with critical illness.
4. Early mobilization is safe, feasible, and sustainable in various ICU populations.
5. The intervention is beneficial, decreasing the incidence and duration of delirium, decreasing ICU and hospital LOS, improving functional status, and increasing the likelihood of being discharged home from the hospital.
6. Early mobilization therapy should be considered in all critically ill patients.

Weakness from inactivity and critical illness is seen commonly in intensive care unit (ICU) patients, occurring in about 57% of patients in at-risk populations.^{1,2} ICU-acquired weakness (ICUAW) develops from inactivity, inflammation, and metabolic abnormalities. Patients' underlying illnesses, safety concerns, the presence of management devices [e.g., intravenous (IV) catheters, endotracheal tubes, thoracostomy tubes], and treatment of pain and anxiety with narcotics and sedation suppress patient activity and further contribute to weakness. The impact of inactivity is powerful, and measurable weakness manifests after just a few days of inactivity.³ In ICUAW, the combination of inactivity, inflammation, and metabolic abnormalities can cause patients to lose 3% to 11% of their strength per day.⁴

CLINICAL MANIFESTATIONS OF ICUAW

The classic case of ICUAW involves a patient with ventilator-dependent respiratory failure and septic shock, requiring several days of sedation, mechanical ventilation, and vasopressors. After the resolution of shock, the patient demonstrates symmetric limb weakness that can manifest as decreased handgrip or leg strength. Such a patient may develop symmetric diaphragmatic weakness, leading to failure to meet criteria for mechanical ventilation liberation despite effective treatment for the initial cause of respiratory failure.

However, ICUAW can develop in any patient, whether or not he or she has respiratory failure or shock. Symmetric limb and diaphragmatic weakness are the most widely identified characteristics. Patients may also demonstrate symmetric sensory loss, muscle atrophy, and decreased deep tendon reflexes, while their facial muscles are often spared.^{5,6} Differential diagnoses include Guillain-Barré syndrome, drug- or metabolism-induced neuropathies, myasthenia gravis, uremia, diabetes, electrolyte abnormalities, brainstem or spinal cord injuries, and epidural abscesses.⁵ Warning: patients with asymmetric findings require additional evaluation to rule out causes of unilateral neuropathy, such as stroke or pressure-induced neuropathy (e.g., pressure over the ulnar or peroneal nerves).

In patients requiring mechanical ventilation, ICUAW may have an even more prolonged effect. Generalized weakness can be tenacious and persistent. Patients often have difficulty recovering normal walking speed and other activities of daily living; limitations on their functional status continue for up to 5 years or more after discharge from the ICU.^{2,4,7,8}

DIAGNOSIS OF ICUAW

A diagnosis is often made by physical examination alone. However, this can be difficult in patients on mechanical ventilation or in those who are otherwise unable to interact with the examining physician. Such patients sometimes require additional testing to rule out other causes. A recent ATS Consensus conference recommends using the Medical Research Council (MRC) scale of Manual Muscle Testing (MMT) as part of the physical examination, even though there are limitations posed by the ordinal scale and the possibility of missing other subtle early changes in distal muscles.^{9,10} The MRC scale is a 6-point assessment of muscle strength that requires full patient cooperation and is graded as follows: 0, no visible contraction; 1, visible contraction without movement; 2, movement of limb, but not against

gravity; 3, movement of limb against gravity; 4, movement of limb against gravity and resistance; and 5, normal power.

MMT is performed on three muscle groups in both the upper and lower extremities. The following movements are included:

- Shoulder abduction (moving the elbows laterally away from the body)
- Elbow flexion
- Wrist extension
- Hip flexion
- Knee extension
- Ankle dorsiflexion

Patients who score 48 or less out of a possible 60 (an average of 4 or less on each group joint) are defined as having ICUAW.^{6,11} Other assessments can include hand dynamometry, which measures hand-grip strength.

Electrophysiologic testing can confirm the suspected diagnosis using nerve conduction studies and electromyography. These tests can be helpful in patients who are unable to follow along with physical examination. In particular, in patients with unexplained failure to liberate from mechanical ventilation, such testing can identify ventilator-induced diaphragmatic dysfunction, a presentation of ICUAW. Electrophysiologic studies are typically reserved for special circumstances that require a diagnosis for management decisions, as they can cause pain and discomfort and require trained staff. Nerve and muscle histology can confirm the diagnosis, but this is rarely indicated because of the risks of biopsy and limited potential benefits.

CLASSIFICATION OF ICUAW

ICU patients can develop pathologic changes in muscles and nerves. As the duration of inactivity increases, disuse leads to physical changes at the cellular level, contributing to diminished action potentials both within nerves and across the neuromuscular junction, resulting in diminished force of contraction, loss of myosin, and muscle atrophy. Simultaneously, the systemic inflammation and metabolic abnormalities of the underlying critical illness cause disruption of microcirculation with damage to nerves and muscles. The nerves can develop dysfunctional nutrient transport. These muscles can develop further atrophy, myosin loss, or even mild rhabdomyolysis. To characterize how individuals are affected, ICUAW can be classified according to physical findings, electrophysiologic testing, or biopsy. Although three distinct classifications exist and are described below, the prevention of ICUAW in all forms responds to early mobilization.

Critical illness polyneuropathy (CIP) affects the distal axonal sensory and motor nerve, impacting both limb and respiratory muscles. Electrophysiologic testing shows reduced amplitude in both muscle and sensory nerve action potentials with normal or mildly reduced nerve conduction velocity.^{6,12}

Critical illness myopathy (CIM) demonstrates both decreased muscle mass and contractility due to decreased myosin in relation to actin and increased proteolysis as compared to protein synthesis. Electrophysiologic testing shows decreased sensory or muscle nerve action potential amplitudes are decreased.^{5,12}

Critical illness neuromyopathy (CINM) demonstrates characteristics of both CIP and CIM on nerve conduction studies and electromyography.^{11,12}

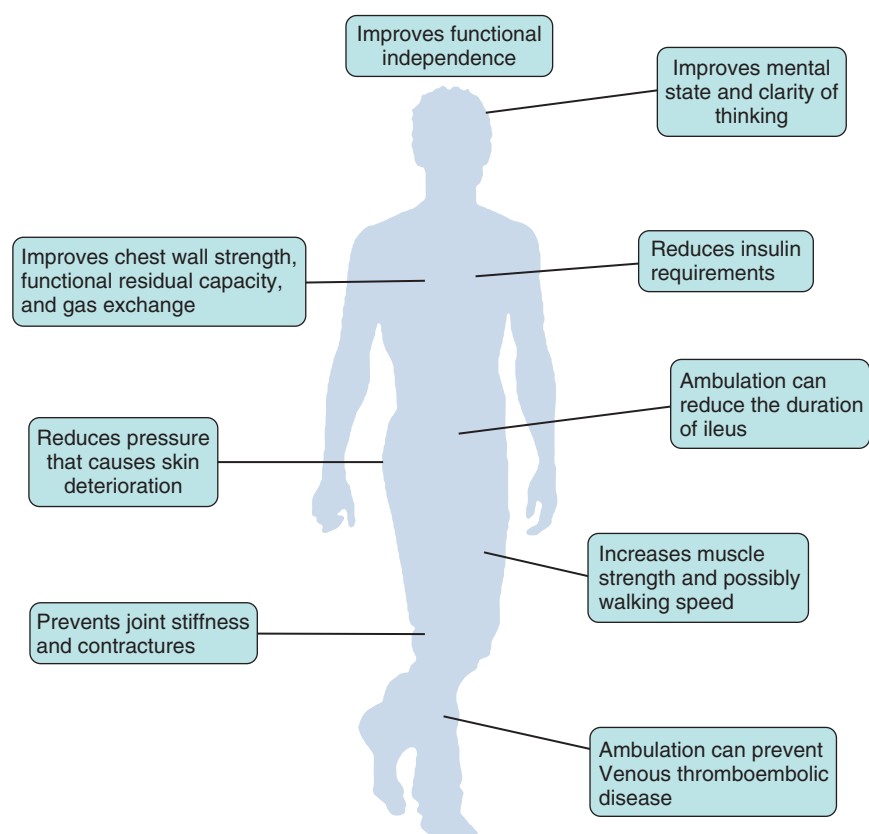

FIGURE 46-1 ■ Benefits of early mobilization.

RISK FACTORS FOR ICUAW

In general, patients are at increased risk the longer they remain mechanically ventilated or on bed rest. Their level of acuity and organ dysfunction also plays a role.¹³ For each day of bed rest, there can be up to a 3% to 11% decrease in strength.⁴ In randomized controlled trials, hyperglycemia was associated with increased risk of ICUAW. Incidence decreased when glucose levels were more closely controlled with insulin protocols in most cases, but not all studies are consistent.^{1,11,14} Corticosteroid usage and neuromuscular blockade were at one time considered to be risk factors; however, more recent studies suggest that they are not. The weakness attributed to corticosteroid impact may actually have resulted from hyperglycemia secondary to the steroid effect on insulin levels.¹¹ Other possible but unconfirmed risk factors include administration of aminoglycosides, female sex, and the use of total parenteral nutrition.¹¹

PREVENTION OF ICUAW

Advantages of Early Mobilization

Prevention of ICUAW by early mobilization is the most important treatment for patients. This should occur before the diagnosis, as soon as safety criteria are met, because early mobilization can have the most benefit for the patient and prevent atrophy secondary to inactivity. Early mobilization programs have been shown to increase patients' functional independence at the time of discharge,¹⁵ yielding improved 6-minute-walk scores and overall perceived well-being.^{16–18} Early mobilization interventions improved patients' metabolic status as evidenced by a decrease in the exogenous insulin required to maintain blood glucose control.¹⁹ Other benefits of early mobilization shown in trials include shortened duration of delirium, reduced need for mechanical ventilation, and shortened stays in the ICU and

TABLE 46-1

Safety Criteria Considerations to Avoid Mobility

- Mean arterial blood pressure <65 mm Hg or target range
- Systolic blood pressure >200 mm Hg
- Heart rate <40 to 50 or >140 beats/min or out of individualized target range
- New arrhythmia
- Patient requires medium or high dose of vasopressor support
- Oxygen requirement of >80%
- PEEP >10 to 15 cm H₂O
- Respiratory rate >35/min for more than 60 seconds
- Oxygen saturation above 90% before initiation
- Oxygen saturation below 85% for >60 seconds or decreasing more than 10% during exercise
- Pain scale rating >7 for more than 5 minutes or equivalent assessment if patient is intubated (i.e., grimacing)
- New-onset chest pain
- Pale appearance, diaphoresis, or feeling acutely ill
- Elevated intracranial pressure
- Agitation
- Undergoing renal replacement therapy
- Active seizures or alcohol withdrawal
- Concern for myocardial ischemia

Adapted from Parry 2012, Needham, D 2010, Schweickert 2009, Hodgson 2013.^{16,18,22,23}

hospital.^{17,18} In practice, it can improve patients' mental clarity and motivation to recover and reduce the possibility of joint stiffness and contractures. Sitting up in a chair and standing can improve gas exchange and functional residual capacity, while ambulating can reduce the skin pressure that can lead to pressure ulcers and the risk of deep vein thrombosis (Fig. 46-1).

Early mobilization can be performed safely in medical and surgical intensive care units by combining clinical judgment with close attention to safety criteria (Table 46-1). In randomized trials, adverse events

such as patient falls, blood pressure fluctuations, and hypoxemia severe enough to require suspension of the treatment occurred in less than 1% of the mobilization sessions.²⁰

Implementation of Early Mobilization in ICU Patients

A multidisciplinary team approach is important to promote working together by physicians, nurses, therapists, and other staff to ensure patient safety and participation. Performing early mobilization interventions on critically ill patients who may be mechanically ventilated is generally considered safe but still requires clinical judgment, individualized safety assessment, and monitoring.²¹ Safety assessment criteria should include oxygen requirements, oxygen saturation, respiratory rate, levels of positive end expiratory pressure, blood pressure, vasopressor requirements, heart rate, intracranial pressures, and other conditions and treatments. See Table 46-1 for details.

Other safety considerations can be tailored to the patient. Additional cardiac concerns include the presence of severe or critical aortic stenosis and dependency on a transvenous or epicardial pacemaker. The presence of other devices, such as a femoral intraaortic balloon pump, extracorporeal membrane oxygenation, pulmonary artery catheterization, or a thoracostomy tube, needs to be considered. Post-surgical or trauma considerations include the presence of a significant unstable fracture or a large, open abdominal or chest wound. Neurologic considerations include elevated intracranial pressure, status post craniectomy, lumbar or subgaleal drain, spinal precautions prior to clearance, active spinal cord injury, vasospasm after aneurysmal clipping, or seizures. Additional medical concerns include bleeding, hypothermia protocol, hyperthermia, and active signs of suboptimal organ perfusion (e.g., elevated lactic acid).²³

Patients should also be assessed for level of consciousness, delirium, and their ability to follow commands. A calm and alert level of consciousness is preferred, as patients who are too drowsy or agitated may

have difficulty following directions. Delirium can be assessed using the Confusion Assessment Method for the ICU (CAM-ICU).²⁴ If patients are not at the appropriate level of consciousness or are delirious, they can be considered for passive range of motion exercises in the upper and lower extremities. Staff or trained family members can perform passive range of motion in the upper and lower extremities. Minimizing the use of sedation and narcotic infusions while maintaining comfort can reduce delirium and improve the level of consciousness and the ability to follow commands.¹⁸

When patients are not delirious and are calm, alert and able to follow commands, they should be ready for active rehabilitation therapy. Physical therapists or other trained staff can conduct early mobilization sessions. Occupational therapy sessions may also be indicated based on personalized need if patients require assistance with finer motor movements.²⁵ Patients will vary significantly in their strength level, ranging from 0-5 on the MRC scale. Personalized therapy sessions are personalized depending on strength and functional abilities and often incorporate a graduated intensity program and up to five to seven sessions per week.

Rehabilitation includes assistance to perform the following activities:

- Transition from lying to sitting on the edge of the bed
- Transition from sitting to standing
- Transfer from standing to sitting in a chair
- Walking with assistance
- Walking independently
- Climbing stairs

In patients who demonstrate more severe deconditioning and weakness, additional strengthening rehabilitation exercises are indicated. These include active trunk and upper and lower extremity exercises that are introduced in a graduated manner.^{17,26} Such programs are often implemented in a multidisciplinary approach with involvement by physical therapists, nurses, and nursing assistants. See Figure 46-2, which is based on modified work by Hanekom et al.

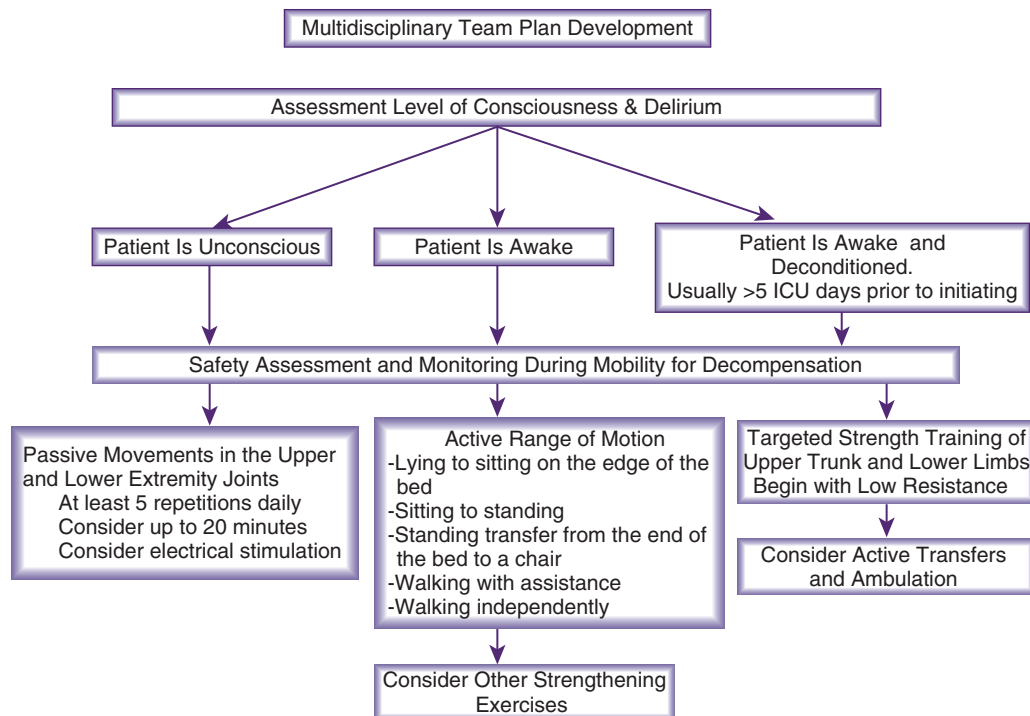

FIGURE 46-2 ■ Implementing early mobilization. (Adapted from Hanekom S, Gosselink R, Dean E, et al. The development of a clinical management algorithm for early physical activity and mobilization of critically ill patients: synthesis of evidence and expert opinion and its translation into practice. Clin Rehabil 25[9] 771–787, 2001.)

Additional Considerations for Prevention of ICUAW

Glycemic Control

Adequate maintenance of glucose control may prevent the development of CIP and CIM. Subanalyses of two randomized controlled trials compared patients with strictly regulated blood sugar to a control group; using electrophysiologic testing, the relative risk of developing ICUAW was more than 20% lower in patients with strictly controlled glucose. Glucose control can minimize the risk of ICUAW in patients who develop hyperglycemia subsequent to receiving corticosteroids.^{14,15,27} While these glucose studies demonstrate theoretical benefits, there is debate about whether the associated risks of hypoglycemia with tight glucose control are justified.¹¹

Inspiratory Muscle Strength Training

Patients who are unable to liberate from mechanical ventilation due to ICUAW may benefit from inspiratory muscle strength training, inhaling against a device that provides resistance to inspiration. In one trial, patients with tracheostomies who required intermittent ventilation received inspiratory muscle strength training of 6-10 resisted breaths repeated four times daily. This trial demonstrated strengthened inspiratory muscle strength and a 25% increase in successful liberation from mechanical ventilation compared to the control group.²⁸

Transcutaneous Electrical Stimulation

Transcutaneous electrical stimulation of the extremities is an intervention that can be used in both unconscious and awake patients and may be of benefit with or without additional active exercises. A limited trial involving daily application of transcutaneous electrical stimulation for 55 minutes to the lower limbs demonstrated improved strength and muscle mass.²⁹ Other small trials also demonstrated improved muscle strength; while debate over the evidence is ongoing, these trials assert that transcutaneous electrical stimulation in conjunction with physical therapy appears to improve outcomes.^{20,30}

Cycle Ergometry

A cycle ergometer is a stationary cycle that offers both active and passive exercise options to a patient. It can provide adjustable resistance for active strengthening or, depending on the patient's ability, can provide passive range of motion to prevent contractures in a weak or paralyzed patient. Patients can use a cycle ergometer while in bed. Research trials have demonstrated improvements in muscle mass.²⁰

CONCLUSION

Patients develop ICUAW disuse atrophy, as well as metabolic and inflammatory injury to the muscles and nerves leading to symmetric

limb weakness and, potentially, diaphragmatic weakness. The duration of inactivity is the leading risk factor, despite the various pathophysiology and electrophysiology findings. The short-term implications of ICUAW include prolonged mechanical ventilation and ICU length of stay. In the long term, weakness and decreased physical abilities can persist for 5 years or more after ICU discharge.

Early mobilization should be initiated as soon as safely possible. Waiting to initiate mobilization can make a significant impact on short- and long-term morbidity. Early mobilization requires close monitoring to ensure patients are able to safely initiate and follow through with the rehabilitative exercises. Most patients can, at the very least, receive passive range of motion exercises and graduated active rehabilitation as they recover from their critical illness. Early mobilization of patients with regular sessions, up to 6-7 times a week, can prevent the morbidity of ICUAW and improve physical health outcomes.

KEY POINTS

1. ICUAW develops from a combination of deconditioning, inflammation, and metabolic disorders.
2. ICUAW manifests with symmetric limb and/or diaphragm weakness with other possible findings that can include sensory loss.
3. Other diagnoses should be considered if the patient has unilateral or facial weakness or the severity is out of proportion to their risk factors.
4. Days of bed rest is the most important risk factor and potentially modifiable with early mobilization. Other important risk factors include the level of acuity and hyperglycemia.
5. Minimizing the use of sedation to promote consciousness for active rehabilitation is important.
6. Early mobilization with 5 to 7 sessions per week can improve patients' strength, physical functioning, and reduce the risk of other comorbid conditions.
7. Early mobilization should be started as soon as it is safe by incorporating the existing criteria.
8. A multidisciplinary team approach is important to implement a graduated and individualized approach for mobilization and physical rehabilitation.

Little can be done to reverse the primary brain damage caused by an insult; however, one of the major factors influencing outcome in patients with acute brain injury is the additional brain damage that occurs from secondary injury processes. Intracranial hypertension and cerebral ischemia are the most significant secondary injury processes that can be monitored and treated in the intensive care unit (ICU). In addition, secondary ischemic insults of extracerebral origin (e.g., arterial hypotension, hypoxemia) can be prevented or treated before they become severe enough to injure the brain. The purpose of advanced monitoring of the brain in the ICU is to detect these secondary insults, allowing for a more informed, individualized approach to treatment.

MONITORING NEUROLOGIC STATUS

The clinical approach to a patient with a neurologic problem requires the physician to have a specialized anatomic and physiologic knowledge of the nervous system. Daily evaluation of neurologic and mental status should be included in the neuromonitoring protocol. Neuro-monitoring should include the Glasgow Coma Scale (GCS) score, function of pyramidal and extrapyramidal systems, status of cranial nerves, function of the cerebellum and spinal cord whenever possible, and any changing trend in the neurologic status. In critically ill patients, such a complete neurologic evaluation can sometimes be unreliable or impossible because of the use of sedatives and the need for intubation and ventilatory support as part of the medical treatment of the neurologic problem. However, in the nonsedated patient, the recently devised Full Outline of Unresponsiveness (FOUR) score, which measures ocular and limb responses to commands and pain, pupillary responses, and respiratory pattern,¹ may provide a more complete assessment of brainstem function. The FOUR score has been shown to have good interrater reliability and prognostic content for some neurologic conditions.² However, experience with this instrument is still limited as compared to the GCS. Current evidence suggests that both the GCS and FOUR score provide useful and reproducible measures of neurologic state and can be routinely used to chart trends in clinical evaluation. Pupillary evaluation is a strong predictor of outcome that must be integrated into the daily GCS evaluation. However, poor interrater reliability exists among practitioners when it comes to pupillary assessment. New devices like the handheld pupillometer provide objective measurement of pupillary response and diameter, but more clinical experience is needed to determine if they should be included as a standard of care.³

Along with neurologic examination, information about vital signs and key laboratory values should be immediately available in a 24-hour record sheet or electronic medical record. Assessment of pain and sedation can be challenging in the context of brain injury. New evidence recommends the use of validated and reliable scales such as the Sedation-Agitation Scale (SAS) and Richmond Agitation Sedation Scale (RASS),⁴ as these provide workable solutions in some patients.

"Wake-up tests" in patients with intracranial hypertension pose significant risks⁵ and show no proven benefits in terms of duration of mechanical ventilation, length of ICU and hospital stay, or mortality rate in patients with neurologic disorders.

The GCS is used as a standardized scale for recording neurologic status in the ICU. The Glasgow Outcome Scale (GOS) has been the

standard outcome tool for neurocritical care. New tools such as the Neurological Outcome Scale for TBI (NOS-TBI) have been adapted for traumatic brain injury (TBI) patients from the National Institutes of Health Stroke Scale (NIHSS).⁶ This scale has demonstrated adequate predictive validity as well as sensitivity to change compared with gold-standard outcome measures and may enhance prediction of outcome in clinical practice and research.⁷

INTRACRANIAL PRESSURE AND CEREBRAL PERFUSION PRESSURE

The threshold that defines normal or raised intracranial pressure (ICP) is uncertain, but normal resting ICP in an adult is considered to be less than 10 mm Hg. Intracranial hypertension is generally accepted to be an ICP greater than 20 to 25 mm Hg. In the 2007 Guidelines for the Management of Severe TBI, an ICP threshold above 20 to 25 mm Hg was adopted as a level III recommendation to initiate treatment to reduce ICP in patients with severe life-threatening head injury.⁸ Recently, the necessity of ICP monitoring was questioned by the BEST-TRIP trial.⁹ No significant difference in outcome was observed when treatment of patients with severe TBI was guided either by ICP monitor or by clinical/imaging judgment. However, the results are specific to certain populations and may not be generalizable. ICP treatment is important, and in circumstances where adequate resources are available, such treatment is best achieved by the combined use of ICP monitoring, clinical examination, and imaging modalities.¹⁰

Cerebral perfusion pressure (CPP) is the difference between the mean arterial blood pressure (MAP) and ICP. Under normal physiologic conditions, an MAP of 80 to 100 mm Hg and an ICP of 5 to 10 mm Hg generate a CPP of 70 to 85 mm Hg.¹¹ Cerebral blood flow (CBF) is determined by both CPP and cerebrovascular resistance (CVR) according to the formula $CBF = CPP/CVR$.

Under normal circumstances, the brain is able to maintain a relatively constant CBF of approximately 50 mL per 100 g/min over a wide range of CPP (60 to 150 mm Hg).¹² Following injury, the ability of the brain to pressure autoregulate can be impaired, and CBF is often dependent on CPP.

The recommendations for an adequate CPP have changed over time and may in part be associated with the variability in how MAP is measured.¹³ Moreover, management strategies based on targeting CPP rather than ICP have not enhanced outcomes.¹⁴ The current recommendation in TBI is to target CPP values within the range of 50 to 70 mm Hg.¹⁵ CPP values less than 50 mm Hg increase the risk of cerebral ischemia and hypoperfusion, while therapies required to maintain CPP values greater than 70 mm Hg have been associated with an increased risk of acute respiratory distress syndrome (ARDS).¹⁶ However, individual assessment may be needed to determine the ideal CPP values for specific populations.¹⁷

Intracranial Pressure Monitoring Devices

The current gold standard for ICP monitoring is the ventriculostomy catheter or external ventricular drain (EVD), which is a catheter inserted in the lateral ventricle, usually via a small right frontal burr hole. This ventricular catheter is connected to a standard pressure transducer that must be maintained at a specific level. The reference

point for ICP is the foramen of Monro, although in practical terms, the external auditory meatus is often used as a landmark. Advantages of EVDs include the ability to measure global ICP and to perform periodic in vivo external calibration and therapeutic CSF drainage and sampling. However, intraventricular catheters are also associated with the highest rate of infection among the ICP monitors. Several microtransducer-tipped ICP monitors are now available on the market for clinical use (e.g., Camino ICP monitor, Codman microsensor, Hummingbird ICP, and Neurovent-P ICP monitor). These catheter-based transducers can measure pressure directly in the brain parenchyma. Although there are fewer risks of infection and intracranial hemorrhage with these catheters, the main disadvantage is that only the Hummingbird ICP can be calibrated in vivo; after preinsertion calibration, they may exhibit zero drift (degree of difference relative to zero atmospheres) over time.¹⁸

Noninvasive ICP monitoring devices have been developed to reduce the risk associated with invasive monitors. Such technologies include displacement of the tympanic membrane,¹⁹ optical detection of cerebral edema,²⁰ transcranial Doppler pulsatility index, and magnetic resonance of the optic nerve sheath.²¹⁻²⁴ So far, none of these methods has provided accuracy sufficient to replace invasive monitors.

ICP Waveforms

The normal ICP waveform consists of three arterial components superimposed on the respiratory rhythm. The first arterial wave is the percussion wave, which reflects the ejection of blood from the heart transmitted through the choroid plexus in the ventricles. The second wave is the tidal wave, which reflects brain compliance; and the third wave is the dicrotic wave that reflects aortic valve closure. Under physiologic conditions, the percussion wave is the tallest, with the tidal and dicrotic waves having progressively smaller amplitudes. When intracranial hypertension is present, cerebral compliance is diminished. This relationship is reflected by an increase in the peak of the tidal and dicrotic waves exceeding that of the percussion wave (Fig. 47-1).

Complications

Among the complications related to ICP monitoring, intracranial hemorrhage and infections are the most common. Less frequent complications are malfunction, malposition, and obstruction. Although these complications generally do not produce long-term morbidity in patients, they can cause inaccurate ICP readings and may increase hospitalization costs by requiring replacement of the monitor.

The incidence of infection for ICP devices is reported to be 1% to 27%,²⁵ depending on the type of device. In 2004, Anderson investigated complications associated with use of an ICP fiberoptic device (Camino) alone and in combination with an EVD catheter; the infection rates were 1.8% and 7.9%, respectively.²⁶ Several other factors have been identified that may affect the risk of EVD infection: the use of prophyl-

actic parenteral antibiotics; presence of other concurrent systemic infections; presence of intraventricular or subarachnoid hemorrhage (SAH); duration of monitoring; open skull fracture, including basilar skull fractures with CSF leak; leakage around the ventriculostomy catheter; and repeated flushing of the EVD. Routine exchange of ventricular catheters and prophylactic antibiotic use for EVD placement are not recommended to reduce infection rates.²⁷ However, placement of ICP monitors should be done under the most sterile possible conditions, minimizing excessive manipulation and flushing. Although there is evidence that antibiotic-impregnated catheters may decrease infection rates, more trials should be conducted to evaluate the beneficial effect on clinical outcome.²⁸

The second most common complication related to ICP monitoring is intracerebral hemorrhage; the risk is very low, with an average incidence of 1.1%.

JUGULAR VENOUS OXYGEN SATURATION

Placement of a jugular venous oxygen saturation ($Sjvo_2$) catheter involves retrograde insertion into the internal jugular vein of a catheter equipped with an oxygen sensor at the tip. The catheter is similar to the type used for CVP monitoring but is directed cephalad into the jugular bulb.²⁹ The tip of the catheter must be placed above the C1-C2 vertebral bodies to avoid contamination with blood coming from the facial vein. Correct positioning of the catheter can be confirmed with a lateral skull x-ray (Fig. 47-2). The incidence of complications related to the $Sjvo_2$ catheter is low but includes carotid artery puncture, hematoma formation, infection, thrombosis, and increased ICP that may arise during catheter insertion or with prolonged monitoring.

The development of in vivo reflectance oximetry using fiberoptic catheters has allowed continuous monitoring of $Sjvo_2$ without the need for continuous blood sampling, except for calibration purposes.³⁰ Changes in $Sjvo_2$ should be confirmed by measuring the oxygen saturation in a blood sample withdrawn from the jugular venous catheter, and the catheter should be recalibrated if the difference is more than 4% to increase the duration of good-quality records.^{29,31}

Side of Jugular Catheterization

The International Consensus on Multimodal Monitoring in Neurocritical Care recommends that the catheter site placement be based on the diagnosis, the type and location of brain lesions, and technical feasibility.¹⁰ If the strategy is to use $Sjvo_2$ as a monitor of global oxygenation, then cannulating the dominant jugular vein is logical because it is most representative of the whole brain. The dominant internal jugular vein is the larger of the two veins as determined by ultrasound imaging or by ICP response to venous compression. However, if the strategy is to identify the most abnormal oxygen saturation, then the side with the most severe injury should be cannulated.³²

Normal Jugular Venous Oxygen Saturation

$Sjvo_2$ reflects the global balance between cerebral oxygen delivery (supply) and the cerebral metabolic rate of oxygen (demand). When arterial oxygen saturation, hemoglobin concentration, and the hemoglobin dissociation curve remain stable, $Sjvo_2$ generally parallels changes in CBF. Values defining the normal range of $Sjvo_2$ are usually considered to be 50% to 54% for the lower range and 75% for the upper range.^{30,33} Multiple pathologic clinical scenarios may cause an increase or decrease in $Sjvo_2$ values (Table 47-1). A large number of studies have assessed the role of jugular venous saturation monitoring in patients with severe TBI. In 1992, Sheinberg et al. demonstrated that single or multiple episodes of jugular venous desaturation were associated with a higher mortality rate.³⁴ However, high $Sjvo_2$ values indicating low cerebral oxygen extraction have also been associated with poor outcome,³³ and an elevated mean arteriojugular oxygen content difference has been associated with a better outcome.³⁵ Because $Sjvo_2$

FIGURE 47-1 ■ (Upper tracing) Normal intracranial pressure (ICP) waveform and its components, W1 (percussion wave), W2 (tidal wave), and W3 (dicrotic wave). (Bottom tracing) As ICP increases, distinctive waveform changes occur (e.g., elevation of the second pulse wave and “rounding” in the ICP waveform).

FIGURE 47-2 ■ **A**, Lateral skull x-ray confirming adequate SjvO₂ catheter placement at the C1-C2 level. **B**, Head computed tomography scan showing the catheter tip correctly placed at the jugular venous bulb level.

TABLE 47-1

Clinical Conditions Associated With Alterations in SjvO₂ Values

| | |
|-----------------------------|--|
| Increased SjvO ₂ | Restricted oxygen diffusion or extraction due to neuronal infarction or inflammation Decreased cerebral metabolism Increased systemic oxygen supply due to hyperoxia Hyperemia |
| Decreased SjvO ₂ | Local or systemic hypoperfusion (e.g., intracranial hypertension, shock or prolonged hypotension, vasospasm) Decreased systemic oxygen supply (e.g., low PaO ₂) Increased cerebral metabolism or oxygen extraction (e.g., seizures, fever) |

provides only information of a global state of cerebral oxygenation, focal ischemic areas are not evaluated with this technique. According to the most recent consensus for brain oxygen monitoring and thresholds, evidence supports the use of SjvO₂ along with clinical indicators and other monitoring modalities for accurate prognostication.¹⁰

■ LOCAL OR REGIONAL MONITORING

Transcranial Doppler Flow Velocity and Flow Volume

Transcranial Doppler (TCD) ultrasonography is a noninvasive monitoring technique that measures blood flow velocity in one of the major arteries at the base of the brain. A 2-MHz pulsed ultrasound signal is transmitted through the skull (usually through the temporal bone) and, using the shift principle, measures red cell flow velocity. Flow volume is directly proportional to flow velocity and can be calculated by multiplying the velocity by the cross-sectional area of the vessel insonated. Cerebral vasospasm is a major cause of disability after SAH and TBI, with similar incidence in both groups.³⁶ The incidence of critical regional CBF reductions due to vasospasm are seen progressively when flow velocities above 120 cm/sec are present by TCD examination.³⁷ Angiography remains the gold standard for diagnosing cerebral vasospasm, but TCD ultrasonography gives a noninvasive alternative for daily bedside monitoring of the CBF dynamics. The

Lindegaard ratio (middle cerebral artery-to-extracranial internal carotid artery flow velocity ratio) helps in differentiating vasospasm from hyperemia; vasospasm is considered to be present if the Lindegaard index is greater than 3:1.³⁸ In hyperemia, the flow velocity for both intracranial and extracranial vessels increases, whereas in vasospasm, high flow velocity is seen only in intracranial vessels, resulting in a high ratio.

Vasospasm following TBI or SAH has an impact on morbidity and mortality. Frequently, the first clinical sign is a deterioration in the neurologic examination, which occurs too late to reverse the process. TCD ultrasonography may identify changes in flow velocity that can precede these clinical findings and may lead to further diagnostic assessment and therapy. The major drawback of TCD ultrasonography is that it is operator dependent, though color-coded TCD provides improved accuracy of measurement.

TCD studies have high specificity for the confirmation of brain death. Brief systolic forward flow spikes with reversed or absent diastolic flow found bilaterally or in three different arteries are accepted TCD criteria for supporting the diagnosis of brain death.³⁹

Brain Tissue Oxygen Partial Pressure

A major limitation of SjvO₂ technology is that regional ischemia cannot be identified. Following TBI and other neurosurgical conditions, regional differences in CBF occur commonly, giving brain tissue oxygen partial pressure (Pbto₂), which measures oxygen levels in the local area of brain surrounding the catheter.

Pbto₂ is measured using a polarographic Clark-type electrode at the tip of a catheter placed in the brain parenchyma. The Clark electrode polarographic probe has a semipermeable membrane covering two electrodes. In the presence of dissolved oxygen crossing the membrane, an electric current is generated and then transferred to a monitor for interpretation. Temperature is also needed to calculate the oxygen tension. Brain temperature rather than core temperature is preferred for this purpose, and a sensor is incorporated into the Pbto₂ catheter.⁴⁰

Normal values for Pbto₂ are 20 to 40 mm Hg; levels below 10 to 15 mm Hg are considered critical, and intervention should be considered.⁴¹ The likelihood of death following a severe TBI increases the longer the Pbto₂ remains below 15 mm Hg and with any occurrence of Pbto₂ below 6 mm Hg.⁴²

Correct probe placement and depth into the region of interest are key for successful monitoring of Pbto₂. Two general strategies have been used for placement of this probe. Some recommend placement

of the probe into relatively normal brain tissue so that the Po_2 values reflect global brain oxygenation. Changes in Pbto_2 correlate well with changes in Sjvo_2 when the sensor is inserted into noncontused areas of the brain. Others recommend placement of the probe into penumbral tissue so that Po_2 values reflect oxygenation in the most vulnerable areas of the brain. Regardless of the strategy used, the Po_2 values must be interpreted with the understanding that the values measure only the local tissue surrounding the catheter. Pbto_2 monitoring is safe and provides accurate data for up to 10 days and can be used to guide pharmacologic, hemodynamic, or respiratory therapy.⁴³ For TBI patients, Pbto_2 monitoring has been incorporated into an overall management strategy, along with ICP and other standard monitoring. Decreased mortality in TBI patients managed using a Pbto_2 -targeted management strategy (maintaining $\text{Pbto}_2 > 25$ mm Hg) has been reported.⁴⁴ Narotam et al. also reported an improved 6-month clinical outcome over the standard ICP/CPP-directed therapy when treatment of cerebral hypoxia with a Pbto_2 -directed protocol (>20 mm Hg) was aggressive.⁴⁵ Treating a reduced Pbto_2 should be first directed to any underlying causes of inadequate cerebral oxygen delivery. Such corrections might include increasing CPP (reducing ICP, increasing MAP), improving arterial oxygenation, transfusions for a low hemoglobin concentration, reducing fever, or treating subclinical seizures. If an underlying cause for the low Pbto_2 is not found, or if Pbto_2 remains low after optimizing oxygen delivery, obtaining a follow-up CT scan of the head might be considered to assess whether a delayed hematoma or hemorrhagic contusion has developed. A sustained (>30 min) Pbto_2 of 0 mm Hg and no response to oxygen challenge are consistent with brain death,⁴⁶ although care related to interpretation in this regard is needed depending on the location of the probe or potential probe malfunction.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) is based on the fact that light in the near-infrared range (700–1000 nm) can pass through skin, bone, and other tissues relatively easily. Oxygenated hemoglobin, deoxygenated hemoglobin, and cytochrome *aa3* have different absorption spectra (650–800 nm). Changes in the absorbance of near-infrared light as it passes through these compounds can be quantified using a modified Beer-Lambert law, which describes optical attenuation. The main advantage of NIRS is that it is a noninvasive method for estimating regional changes in cerebral oxygenation. However, its clinical use is limited by an inability to differentiate between intracranial and extracranial changes in blood flow and oxygenation. This shortcoming adversely affects the reliability of the readings⁴⁵ and causes an inconsistent association between monitoring of decreased oxygenation and neurologic outcome.⁴⁷ Currently, there are no studies providing evidence that NIRS use alone can influence outcomes in adult neurocritical care.

Electroencephalogram

An electroencephalogram (EEG) depicts the spontaneous electrical activity of the cerebral cortex and is generated mainly by the summation of excitatory and inhibitory postsynaptic potentials of cortical neurons. It does not reflect activity in subcortical levels, cranial nerves, or the spinal cord. The electrical signal is amplified, filtered, and then displayed as either 8 or 16 channels (8 channels per hemisphere) to give an accurate representation of electrical activity throughout the cortex. EEG activity is usually interpreted in terms of frequency, amplitude, and location (focal or generalized activity).

EEG is the most frequently used electrophysiological technique in the ICU. EEG offers information about brain electrical activity and is essential to detect seizures. The presence of seizures, including duration and response to therapy, may predict outcome after coma with or without known acute brain injury in the ICU setting.⁴⁸ A relatively high incidence of nonconvulsive seizures (NCSz) occurs in the ICU (approximately 30%); such seizures can only be detected with EEG.

Setting a low threshold for obtaining an EEG must be considered in patients with acute brain injury and unexplained alteration of consciousness. EEG is urgently needed in patients with convulsive status epilepticus who remain unresponsive after one hour of administering what should represent adequate antiepileptic treatment. Continuous EEG (cEEG) is also strongly recommended in patients undergoing therapeutic hypothermia and within 24 h of rewarming to exclude NCSz in all comatose patients after cardiac arrest.⁴⁹

Continuous or long-term EEG is usually preferred over routine EEG recordings, as routine EEG will miss NCSz in approximately half of those with seizures when compared to prolonged monitoring.⁵⁰ Quantitative EEG algorithms have been developed to support the time-consuming expert review of cEEG recordings in the ICU setting. However, none of these techniques has reliably replaced the invaluable role of the expertly trained electrophysiologist.

Microdialysis

Microdialysis is a technique for sampling the extracellular space of a tissue. This method is based on the diffusion of water-soluble substances through a semipermeable membrane. Small molecules ($<20,000$ D) from the extracellular fluid can diffuse across the membrane and enter the perfusate. Conversely, substances that have been added to the perfusate can diffuse across the membrane to gain entry to the tissue. The degree of permeability of the membrane determines the molecular weight of the substances that cross it.

The concentration of substances in the dialysate depends on the flow rate and chemical composition of the perfusate, the length of the dialysis membrane, the type of dialysis membrane, and the diffusion coefficient of the tissue. The recovery of a particular substance is defined as the concentration in the dialysate divided by the concentration in the interstitial fluid. If the membrane is long enough and the flow slow enough, the concentration in the perfusate will be the same as that in the interstitial fluid (i.e., 100%). The parameters that are commonly used in clinical studies (i.e., 10-mm membrane, perfusion with Ringer's solution, and flow rate of 0.3 $\mu\text{L}/\text{min}$) provide an *in vivo* recovery rate (extrapolation to zero flow method) of approximately 70%.⁵¹

The technique of cerebral microdialysis allows continuous and online monitoring of changes in brain tissue chemistry. As with brain tissue oxygenation monitoring, microdialysis involves inserting a fine catheter (diameter 0.62 mm) into the brain. The dialysate, which is collected in vials that are exchanged every 10 to 60 minutes, is then analyzed using sensitive assays.

The key substances measured by microdialysis can be categorized as follows:

1. Energy-related metabolites (glucose, lactate, pyruvate, adenosine, xanthine)
2. Neurotransmitters (glutamate, aspartate)
3. Markers of tissue damage and inflammation (glycerol)
4. Exogenous substances (administered drugs)

Metabolite variations over time can help with clinical management and are not limited to markers of ischemia but allow monitoring of energy metabolism in the brain as well. In TBI, cerebral microdialysis may contribute to prognostication.⁵² In SAH, microdialysis has provided an understanding of poor energy substrate transport and of markers of late cerebral ischemia. Cerebral microdialysis has a very low complication rate. Nonetheless, there are a number of limitations regarding its clinical use, including its focal measurement and the fact that it discloses different metabolite concentrations when inserted into pathologic versus preserved brain areas. Therefore, microdialysis should be interpreted based on the location as defined by postinsertion CT. Currently available techniques can be cumbersome for bedside monitoring and interpretation, providing delayed rather than real-time data. Microdialysis when used with multimodality monitoring may enhance the understanding of brain physiology. Similarly, when used for research, it may provide new understandings of pathophysiologic mechanisms and treatment modalities that directly affect brain metabolism and function.

KEY POINTS

1. Evaluation of neurologic and mental status should be included in the monitoring protocol whenever possible.
2. The ventriculostomy catheter remains the preferred device for monitoring intracranial pressure (ICP) and is the standard against which all new monitors are compared.
3. The two major complications of ICP monitoring are ventriculitis and intracranial hemorrhage.
4. The simplest measure of cerebral perfusion is cerebral perfusion pressure (CPP). For equivalent levels of CPP, cerebral perfusion is impaired more by decreases in blood pressure than by increases in ICP.
5. Transcranial Doppler (TCD) ultrasonography is a noninvasive monitor that provides indirect information about cerebral blood flow (CBF) in one of the major arteries at the base of the brain. In the absence of vessel stenosis, vasospasm, or changes in arterial blood pressure or blood rheology, pulsatility reflects the distal cerebrovascular resistance.
6. The Lindegaard (hemispheric) index is the ratio of flow velocity in the middle cerebral artery and the internal carotid artery. The mean hemispheric index in normal individuals is 1.76 ± 0.1 , and pathologic values suggestive of vasospasm are generally above 3.
7. Normal values for P_{bto_2} are 20 to 40 mm Hg, and critical reductions are below 10 to 15 mm Hg.
8. The use of electroencephalograms (EEGs) in the ICU to detect early subclinical seizures may help reduce mortality and morbidity in status epilepticus. Continuous EEG monitoring is also useful in detecting ischemic cerebral events, including vasospasm following subarachnoid hemorrhage (SAH) and intracranial hypertension after TBI.

Altered states of consciousness are a common reason for the admission to intensive care units (ICUs). Few problems are more difficult to manage than the unconscious patient, because there are many potential causes of an altered mental status, and the time for diagnosis and effective intervention is short. *Consciousness* is defined as the state of awareness of the self and the environment. Consciousness requires two intact and interdependent physiologic and anatomic components: (1) arousal (or wakefulness) and its underlying neural substrate, the ascending reticular activating system (ARAS) and diencephalon, and (2) awareness, which requires the functioning cerebral cortex of both hemispheres. Most disorders that acutely disturb consciousness are impairments of arousal that create circumstances under which the brain's capacity for consciousness cannot be accurately assessed. In other words, failure of arousal renders it impossible to test awareness.

Alterations in arousal may be transient, lasting only several seconds or minutes (following seizures, syncope, and cardiac dysrhythmia), or sustained, lasting hours or longer. Four terms describe disturbed arousal of a patient. *Alert* refers to a normal state of arousal. *Stupor* describes a state of unarousability in which strong external stimuli can transiently restore wakefulness. Stupor implies at least a limited degree of cognitive activity accompanies the arousal, even if transient. *Coma* is characterized by an uninterrupted loss of the capacity for arousal. The eyes are closed, sleep/wake cycles disappear, and even vigorous stimulation elicits only reflex responses at best. *Lethargy* describes a range of behaviors between arousal and stupor. Only the terms *alert* and *coma* have enough precision to be used without further qualification; a coma has gradations in depth, but this cannot be accurately assessed once the patient no longer responds to external stimuli. Stupor and coma imply an acute or subacute brain insult. The cerebral reserve capacity is large, and thus, altered consciousness reflects either diffuse and bilateral cerebral dysfunction, failure of the brainstem-thalamic ARAS, or both. All alterations in arousal should be regarded as acute and potentially life-threatening emergencies.

The evaluation of a comatose patient demands a systematic approach with directed diagnostic and therapeutic endeavors; time should not be wasted on irrelevant considerations. Urgent steps are required to minimize permanent brain damage from reversible causes. Patient evaluation and treatment must occur simultaneously. Such an approach demands an understanding of the pathophysiology of consciousness, and mechanisms by which it may be deranged.

ANATOMY, PATHOLOGY, AND PATHOPHYSIOLOGY

Consciousness depends on an intact ARAS in the brainstem and adjacent thalamus, which acts as the alerting or awakening element of consciousness, together with a functioning cerebral cortex of both hemispheres, which determines the content of that consciousness.^{1,2} The ARAS lies within a more or less isodendritic core that extends from

the medulla through the tegmentum of the pons to the midbrain and paramedian thalamus. The system is continuous caudally with the reticular intermediate gray matter of the spinal cord and rostrally with the subthalamus, hypothalamus, anterior thalamus, and basal forebrain.³ The ARAS itself arises within the rostral pontine tegmentum and extends across the mesencephalic tegmentum and its adjacent intrathalamic nuclei. ARAS functions and interconnections are considerable, and likely contribute to more than only a cortical arousal system. The specific role of the various links from the reticular formation to the thalamus has yet to be fully identified.⁴ Furthermore, the cortex feeds back on the thalamic nuclei to contribute to an important loop that amplifies arousal mechanisms.^{5,6}

The ascending arousal system contains cholinergic, monoaminergic, and γ -aminobutyric acid (GABA) systems, none of which has been identified as the arousal neurotransmitter.^{2,7,8} Acute structural damage to, or metabolic/chemical disturbance of, either the ascending brainstem-thalamic activating system or the thalamocorticothalamic loop can alter the aroused attentive state. Consciousness depends on the continuous interaction between the mechanisms that provide arousal and awareness. The brainstem and thalamus provide the activating mechanism, and the cerebrum provides full cognition and self-excitation. The content of consciousness is best regarded as the amalgam and integration of all cognitive function that resides in the thalamocortical circuits of both hemispheres. Altered awareness is due to the disruption of this cortical activity by diffuse pathology. Focal lesions of the cerebrum can produce profound deficits (e.g., aphasia, alexia, amnesia, and hemianopsia), but only diffuse bilateral damage sparing the ARAS and diencephalon can lead to wakeful unawareness. Thus, there are two kinds of altered consciousness: (1) altered arousal due to dysfunction of the ARAS-diencephalon and (2) altered awareness due to bilateral diffuse cerebral hemisphere dysfunction.

Four major pathologic processes can cause such severe global, acute reductions of consciousness.^{1,9} (1) In the presence of diffuse or extensive multifocal bilateral dysfunction of the cerebral cortex, the cortical gray matter is diffusely and acutely depressed or destroyed. Concurrently, the cortical-subcortical physiologic feedback excitatory loops are impaired, with the result that brainstem autonomic mechanisms become temporarily profoundly inhibited, producing the equivalent of acute "reticular shock" below the level of the lesion. (2) Direct damage to the paramedian upper brainstem and posterior-inferior diencephalic ascending arousal system blocks normal cortical activation. (3) The widespread disconnection between the cortex and subcortical activating mechanisms acts to produce effects similar to both conditions 1 and 2. (4) Diffuse disorders, usually metabolic in origin, concurrently affect both the cortical and subcortical arousal mechanisms, although to a different degree according to the cause.

Structural Lesions Causing Coma

Intracranial mass lesions that cause a coma may be located in the supratentorial or infratentorial compartments. From either location, impaired arousal or coma is caused by the compression of the brainstem-hypothalamic activating mechanisms secondary to swelling and the displacement of deep-lying intracranial contents. The ultimate event occurs either by halting the axoplasmic flow or by sustained neuronal depolarization due to ischemia or hemorrhage. Factors

[†]This chapter is dedicated to Dr. Plum, who passed away prior to the publication of this edition of the textbook.

important to the degree of the loss of arousal are the rate of development, location, and ultimate size of the lesion. Cerebral mass lesions distort the intracranial anatomy and thereby alter the cerebrospinal fluid (CSF) circulation and blood supply to the brain. These changes result in an increased bulk of the injured tissue and a reduction in intracranial compliance. Intercompartmental pressure gradients result in herniation syndromes that are not necessarily associated with large increases in intracranial pressure (ICP). Sustained or evolving mass lesions can disturb cerebral vascular autoregulation, which results in transient vasodilatation. This in turn causes recurrent increases in ICP, with the additional compromise of cerebral blood supply to the injured regions.

Two herniation syndromes demonstrate the mechanism by which supratentorial lesions induce a coma. The rate of evolution of a mass dictates whether the anatomic distortion precedes (in slowly evolving lesions) or parallels the patient's deterioration of wakefulness. *Transtentorial herniation* can be central or predominantly unilateral. Central herniation results from caudal displacement by deep midline supratentorial masses, large space-occupying hemisphere lesions, or large uni- or bilateral compressive extraaxial lesions with compression of the ARAS. The progressive rostral-caudal pathologic and clinical stages of this herniation syndrome were outlined.¹ Pathologically, the bilateral symmetric displacement of the supratentorial contents occurs through the tentorial notch into the posterior fossa. Alertness is impaired early, pupils become small (to 3 mm) and reactive, and bilateral upper motor neuron signs develop. Cheyne-Stokes breathing, grasp reflexes, roving eye movements, or the depressed escape of oculocephalic reflexes are the typical clinical manifestations. In the absence of effective therapy at this diencephalic stage, herniation progresses caudally to compress the midbrain, leading to a deep coma and fixed midposition (3-5 mm) of the pupils, signifying sympathetic and parasympathetic interruption. Spontaneous eye movements cease, and the oculocephalic and oculocephalic reflexes become difficult to elicit. Spontaneous extensor posturing may also occur. Once this stage is reached, full recovery is unlikely. As the caudal compression-ischemia process advances, the pontine and medullary function becomes destroyed, with variable breathing patterns and absent reflex eye movements. Finally, autonomic cardiovascular and respiratory functions cease as the medullary centers fail.

Uncus herniation results from laterally placed hemisphere lesions, particularly of the temporal lobes, that cause side-to-side cerebral displacement as well as transtentorial herniation. Focal hemisphere dysfunction (e.g., hemiparesis, aphasia, seizures) precedes unilateral (usually ipsilateral) compression paralysis of the third cranial nerve. An early sign of uncus herniation is an ipsilateral (rarely contralateral) enlarged pupil that responds sluggishly to light, followed by a fixed, dilated pupil and an oculomotor palsy (eye turned downward and outward).¹ The ipsilateral posterior cerebral artery can become compressed as it crosses the tentorium and causes ipsilateral occipital lobe ischemia. Progressively, the temporal lobe compresses the midbrain, with the loss of arousal and bilateral or contralateral extensor posturing. Ipsilateral to the intracranial lesion, hemiparesis may develop if the opposite cerebral peduncle becomes compressed against the contralateral tentorial edge. Abnormal brainstem signs become symmetric, and herniation proceeds similarly to central herniation as rostrocaudal brainstem displacement progresses.

Infratentorial lesions cause coma by displacement, compression, or direct destruction of the pontomesencephalic tegmental activating system. Displacement of the medulla downward that is sufficient to push the brainstem and cerebellar tonsils into the foramen magnum causes cardiorespiratory collapse. Acute intrinsic lesions of the brainstem, usually hemorrhagic or ischemic, cause an abrupt onset of coma and are associated with abnormal neuro-ophthalmologic findings. Pupils are pinpoint due to the disruption of pontine sympathetic pathways or are dilated due to the destruction of the third cranial nerve nuclei or intraaxial exiting fibers. Disconjugate eye movements and nystagmus often occur while vertical eye movements are relatively spared. Ocular bobbing signifies pontine damage. Upper motor neuron

signs develop, and patients can become quadriplegic; flaccidity in the upper extremities and flexor withdrawal responses in the lower extremities often accompany midbrain-pontine damage.

Pathologically, basilar artery occlusion leads to asymmetric ischemia of the brainstem, with the involvement of the ARAS, the neighboring densely packed neuropil, as well as the descending and ascending motor and sensory tracts. Thrombosis of the rostral basilar artery leads to an infarction of the midline thalamic nuclei and brief coma without other obvious brainstem signs. A hemorrhage into the ventral pons occasionally spares consciousness but produces neuro-ophthalmologic signs and motor dysfunction. Extension of hemorrhage into the rostral pontine tegmentum results in a stupor, coma, or death. Basilar artery migraine can produce altered consciousness, possibly by interfering with blood flow in the basilar artery system. Rapidly developing extensive central pontine myelinolysis may cause a coma by extension into the pontine tegmentum. Other intrinsic brainstem lesions (e.g., tumor, abscess, granuloma, and demyelination) tend to progress slowly and usually spare arousal mechanisms. However, they may reduce attention and other cognitive functions, leading to severe psychomotor retardation.

Posterior extraaxial fossa lesions cause comas by the direct compression of the ARAS in the brainstem and in the diencephalon by upward transtentorial herniation. Compression of the pons may be difficult to distinguish from intrinsic lesions but is often accompanied by a headache, vomiting, and hypertension due to a Cushing reflex. Upward herniation at the midbrain level is initially characterized by a coma, reactive miotic pupils, asymmetric or absent caloric eye responses, and decerebrate posturing; caudal-rostral brainstem dysfunction then occurs, with midbrain failure and midposition fixed pupils.¹⁰ Causes of brainstem compression include cerebellar hemorrhage, infarction, and abscess, rapidly expanding cerebellar or fourth ventricle tumors, or less commonly, infratentorial epidural or subdural hematomas. The drainage of the lateral ventricles to relieve obstructive hydrocephalus due to posterior fossa masses can potentially precipitate upward acute transtentorial herniation.^{11,12}

Downward herniation of the cerebellar tonsils through the foramen magnum causes acute medullary dysfunction, as well as abrupt respiratory and circulatory collapse. Less severe impaction of the tonsils in the foramen magnum can lead to obstructive hydrocephalus and consequent bihemispheric dysfunction with altered arousal. Clinical manifestations include headache, nausea, vomiting, lower cranial nerve signs, vertical nystagmus, ataxia, and irregular breathing. Moreover, a lumbar puncture in this context carries the risk of catastrophic consequences.¹¹

Nonstructural Causes of Coma

Nonstructural disorders (e.g., metabolic or toxic disturbances) produce comas by diffusely depressing the function of the brainstem and cerebral arousal mechanisms. The anatomic locus of metabolic brain diseases has not been clearly defined. The onset of coma can be abrupt, as with toxic drug ingestion, general anesthesia, or cardiac arrest, or it may evolve slowly after a period of confusion and inattention. The chief manifestations of metabolic encephalopathy are disturbances in arousal and cognitive function. Other findings include abnormalities of the sleep/wake cycle, autonomic disturbances, and abnormal breathing variations.

A helpful distinguishing clinical feature of diffuse encephalopathy is the preservation of the pupillary light response; the only exceptions are an overdose of anticholinergic agents, near-fatal anoxia, or self-initiated malingering. Typically, a lack of pupillary reactivity requires a search for an underlying structural lesion. Neurologic examination reveals a decreased level of arousal and widespread cognitive decline. Deeply comatose patients without brainstem or hemisphere function and no known cause for a coma must be assumed to have suffered accidental or intentional poisoning. Metabolic disturbances of arousal and cognition particularly affect elderly patients who suffer from serious systemic illnesses or have undergone complicated surgery.

Multilevel CNS dysfunction characterizes metabolic encephalopathy. At the onset, abnormalities in cognition are at least as severe as the disturbance of arousal. Misperception, disorientation, hallucinations, concentration and memory deficits, and occasionally hypervigilance may progress to profound stupor and coma. The patient's level of arousal and consciousness often fluctuates. Motor abnormalities, if present, are usually symmetric, and patients often suffer from tremors, asterixis, and myoclonus. Spontaneous motor activity may range from hypoactivity (e.g., in cases of sedating drug or endogenous metabolic disturbances) to hyperactivity (e.g., after drug withdrawal or overdose of stimulants). Seizures can occur in cases of alcohol or drug withdrawal and in patients with established cortical pathology. Focal seizures may occur even without structural disease during hypoglycemia, hepatic encephalopathy, uremia, abnormal calcium levels, or toxin ingestion. Autonomic dysfunction can manifest as hypothermia with hypoglycemia, myxedema, or sedative drug overdose. Hyperthermia can occur in withdrawal states, particularly delirium tremens, anticholinergic drug overdose, infection, neuroleptic malignant syndrome, or malignant hyperthermia.

The metabolic need of the brain largely depends on the oxidation of glucose. Certain fatty acids and ketone bodies can supply part of the metabolic needs in emergency circumstances but fail to meet energy requirements. Normal cerebral blood flow (CBF) is around 55 mL/100 g tissue/min. At CBF < 20 mL/100 g/min, oxygen delivery becomes insufficient for normal levels of oxidative metabolism, and the cerebral glycolytic rate increases. Patients lose consciousness, and the electroencephalogram (EEG) is suppressed secondary to synaptic failure at CBF levels between 16 and 20 mL/100 g/min. The cortical evoked response is abolished below about 15 mL/100 g/min. At a CBF around 8 mL/100 g/min, the energy-dependent membrane pump fails, and the membrane potential collapses. Unless the CBF is restored promptly, irreversible neuronal injury will ensue. However, the threshold for ischemic neuronal injury is time-dependent. The complete cessation of CBF leads to a loss of consciousness in 8 seconds, and EEG suppression occurs between 10 and 12 seconds. ATP exhaustion and ionic pump failure occurs in 120 seconds. Selective neuronal damage starts after periods as brief as 5 minutes, and severe neuronal damage occurs after 20 to 30 minutes. Brain necrosis or infarction begins after 1 to 2 hours.

Under physiologic conditions, glucose is the brain's only substrate and crosses the blood-brain barrier by facilitated transport. The normal brain uses about 55 mg glucose/100 g/min. In adults, hypoglycemia (a blood glucose level <40 mg/dL) produces signs and symptoms of encephalopathy resulting from dysfunction of the cerebral cortex, before the brainstem. Neurologic presentation of hypoglycemia can vary from the focal motor or sensory deficits to a coma. Acute symptoms of hypoglycemia are better correlated with the rate at which the blood glucose levels decrease than with the degree of hypoglycemia. The blood glucose level at which cerebral metabolism fails and symptoms develop varies among individuals, but in general, confusion occurs at levels <30 mg/dL and a coma at <10 mg/dL. The brain stores about 2 g of glucose and glycogen, so a patient in a hypoglycemic coma may survive 90 minutes without suffering irreversible brain damage. The pathophysiology of coma from hypoglycemia is not well understood. The disorder cannot solely be attributed to glucose starvation of the neurons. Rather than such an internal catabolic death, evidence suggests that neurons are killed by external factors. Around the time the EEG becomes isoelectric, endogenous neurotoxins are produced and released by the brain into tissue and CSF. The distribution of necrotic neurons is unlike that of ischemia and is related to white matter and CSF pathways. The toxins first disrupt the dendritic trees, sparing the intermediate axons, an indication of excitotoxic neuronal injury. The exact mechanism of excitotoxic neuronal necrosis may involve hyperexcitation and culminates in the rupture of the cell membrane.

The pathophysiology of other metabolic encephalopathies is less well established and is discussed elsewhere.¹ Hepatic encephalopathy is caused not merely by ammonia intoxication but also involves the

accumulation of neurotoxins, such as short-chain and medium-chain fatty acids, mercaptans, and phenols. Altered neurotransmission may play a role in the accumulation of benzodiazepine-like substances, the imbalance of serotonergic and glutaminergic neurotransmission, and the accumulation of false neurotransmitters. The identity of the neurotoxins involved in uremic encephalopathy is uncertain and includes urea itself, guanidine and related compounds, phenols, aromatic hydroxyacids, amines, various peptide "middle molecules," myoinositol, parathormone, and amino acid imbalance. The cause of the disequilibrium syndrome may entail more than osmotic water shifts. The pathogenesis of pancreatic encephalopathy may involve demyelination of brain white matter due to liberated enzymes from a damaged pancreas, disseminated intravascular coagulation, or fat embolism.

The mechanism of action of exogenous toxins or drugs depends partially on both the structure and the dose. It should also be determined that none of the sedatives taken acutely produces permanent damage to the nervous system, making prompt diagnosis and effective treatment essential.

DIFFERENTIAL DIAGNOSIS

Several different behavioral states appear similar to, and can be confused with, coma. Differentiation of such states from a true coma has important diagnostic, therapeutic, and prognostic implications. Moreover, a coma is not a permanent state; patients who survive an initial coma may evolve through and into these altered behavioral states. All patients who survive beyond the stage of acute systemic complications reawaken and either proceed to recovery (with none or varying degrees of disability) or remain in a vegetative state.

The *vegetative state* can be defined as wakefulness without awareness and is the consequence of various diffuse brain insults.^{1,13} It may be a transient phase through which patients in a coma pass as the cerebral cortex recovers more slowly than the brainstem. Vegetative patients appear to be awake and to have cyclical sleep patterns; however, they do not exhibit evidence of cognitive function or learned behavioral responses to external stimuli. They may exhibit spontaneous eye opening, eye movements, and stereotypic facial and limb movements but are unable to demonstrate speech or comprehension and lack purposeful activity. They generate a normal body temperature and usually have functional cardiovascular, respiratory, and digestive systems but are doubly incontinent. The vegetative state should be termed *persistent* at 1 month after injury and *permanent* at 3 months after nontraumatic injury or 12 months after traumatic injury.^{14,15} Extended observation is required to assess any behavioral responses to external stimulation and demonstrate cognitive unawareness. The EEG is never isoelectric but shows various patterns of rhythm and amplitude, inconsistent from one patient to the next. Normal EEG sleep/wake patterns are absent.

In the *locked-in syndrome*, patients retain or regain arousability and self-awareness, but because of extensive bilateral paralysis (i.e., deafferentation) can no longer communicate except in severely limited ways. Such patients suffer bilateral ventral pontine lesions with quadriplegia, horizontal gaze palsies, and lower cranial nerve palsies. Voluntarily, they are capable only of vertical eye movements and/or blinking.¹ Sleep may be abnormal, with a marked reduction in non-REM and REM phases. The most common etiology is pontine infarction due to basilar artery thrombosis, but others include pontine hemorrhage, central pontine myelinolysis, and mass brainstem lesions. Neuromuscular causes of the locked-in syndrome include severe acute inflammatory demyelinating polyradiculoneuropathies, myasthenia, botulism, and neuromuscular blocking agents. In these peripheral disorders, the upward gaze is not selectively spared.

Akinetic mutism describes a rare subacute or chronic state of altered behavior, in which a patient who appears alert is both silent and immobile but not paralyzed.¹⁶ External evidence of mental activity is unobtainable. The patient usually lies with eyes opened and retains cycles of self-sustained arousal, giving the appearance of vigilance. Skeletal muscle tone can be normal or hypertonic but is usually not spastic.

Movements are rudimentary even in response to unpleasant stimuli. Affected patients are usually doubly incontinent. Lesions that cause akinetic mutism vary widely. One pattern consists of bilateral damage to the frontal lobe or limbic-cortical integration with relative sparing of the motor pathways, and vulnerable areas involve both basal and medial frontal areas. Similar behavior can also follow incomplete lesions of the deep gray matter (paramedian reticular formation of the posterior diencephalon and adjacent midbrain), but such patients usually suffer double hemiplegia and act slowly yet are not completely akinetic or noncommunicative.

Catatonia is a symptom complex associated most often with psychiatric disease. This behavioral disturbance is characterized by stupor or excitement and variable mutism, posturing, rigidity, grimacing, and catalepsy. It can be caused by a variety of illnesses, both psychiatric (affective more than psychotic) disorders, as well as structural or metabolic diseases (e.g., toxic and drug-induced psychosis, encephalitis, and alcoholic degeneration). Psychiatric catatonia may be difficult to distinguish from organic disease because patients often appear lethargic or stuporous rather than totally unresponsive. Such patients also may have a variety of endocrine or autonomic abnormalities. Patients in a catatonic stupor do not move spontaneously and appear unresponsive to the environment despite what appears to be a normal level of arousal and consciousness. This impression is supported by a normal neurologic exam and the subsequent recall of most events that took place during the unresponsive period. Patients usually lie with their eyes opened, may not blink in response to visual threats, but one can usually elicit optokinetic responses. The pupils are semidilated and reactive to light, the oculocephalic reflexes are absent, and vestibulo-ocular testing evokes normal nystagmus. Patients may hypersalivate and be doubly incontinent. Passive movement of the limbs meets with waxy flexibility, and catalepsy is seen in 30% of patients. Choreiform jerks of the extremities and facial grimaces are common. The EEG, both of catatonic excitement and stupor, often shows a reactive, low-voltage, fast-normal record rather than the slow record of a comatose patient.

■ APPROACH TO COMA

The initial approach to stupor and coma is based on the principle that all alterations in arousal are acute, life-threatening emergencies. Urgent steps are required to prevent or minimize permanent brain damage from reversible causes, often before the cause of the coma is established. Patient evaluation and treatment must necessarily occur simultaneously. Serial examinations are needed with accurate documentation, to determine a change in state of the patient. Accordingly, management decisions (therapeutic and diagnostic) must be made. The clinical approach to an unconscious patient logically entails the following steps: (1) emergency treatment; (2) history (e.g., from relatives, friends, and emergency medical personnel); (3) general physical examination; (4) neurologic profile, the key to categorizing the nature of coma; and (5) specific management.

Emergency Management

The initial assessment must focus on the vital signs to determine the appropriate resuscitation measures; the diagnostic process begins later. Urgent, and sometimes empiric, therapy must be administered to avoid additional brain insult.

Oxygenation must be ensured by establishing an airway and ventilating the lungs. The threshold for intubation should be low in the comatose patient, even if the respiratory function is sufficient for proper ventilation and oxygenation: the level of consciousness may deteriorate, and breathing may decompensate suddenly and unexpectedly. An open airway must be maintained and protected from aspiration. While preparing for intubation, maximal oxygenation can be ensured by suctioning the upper airway and manually ventilating with oxygen using a mask and bag. Bag-valve-mask ventilation with 100% oxygen and 1 mg of intravenous (IV) atropine may help prevent cardiac dysrhythmias.

If cervical spine injury is a possibility or has not been excluded, intubation should be performed by the most skilled practitioner available, with cervical spine precautions. A brief neurologic examination is performed before sedation required for intubation.

The key points of the *rapid neurologic exam* are hand drop from over the head (to assess for malingering or hysterical loss of consciousness); pupillary size and response to light; abnormal eye movements (i.e., active disconjugate, unilaterally paralytic, passively induced, or absent); grimacing/withdrawal from noxious stimulation; and abnormal plantar response (unilateral or bilateral Babinski sign).¹⁷ Assisted ventilation should continue during the examination if necessary. Neuromuscular blockade required for patient management and care should be deferred if possible until the neurologic examination is completed (3-5 minutes). Signs of arousal or inadequate sedation include dilated reactive pupils, copious tears, diaphoresis, tachycardia, systemic hypertension, and increased pulmonary artery pressure. Thereafter, head computed tomography (CT) may be required.

Evaluate respiratory excursions: Arterial blood gas measurement is the only certain method to determine adequate ventilation and oxygenation. Pulse oximetry is useful, however, because it provides immediate, continuous information regarding arterial oxygen saturation. The comatose patient ideally should maintain a $\text{PaO}_2 > 100$ mm Hg and a PaCO_2 between 34 and 37 mm Hg. Hyperventilation ($\text{PaCO}_2 < 35$ mm Hg) should be avoided unless herniation is suspected. Unless contraindicated, place a nasogastric tube to facilitate gastric lavage and prevent regurgitation.

Maintain circulation to assure adequate cerebral perfusion. Appropriate resuscitation fluid is normal saline and a mean arterial pressure around 100 mm Hg is adequate and safe for most patients. While obtaining venous access, collect blood samples for anticipated tests (Box 48-1). Treat hypotension by replacing any blood volume loss, and use vasoactive agents. Judiciously manage systemic hypertension with hypotensive agents that do not substantially raise ICP by their vasodilating effect (e.g., labetalol, hydralazine, or a titrated nitroprusside infusion are the favored agents for managing uncontrollable hypertension). For most situations, the systolic blood pressure should not be treated unless it is >160 mm Hg. Maintain the urine output at a minimum of 0.5 mL/kg/h; an accurate measurement requires bladder catheterization.

Glucose and thiamine: Hypoglycemia is a frequent cause of altered consciousness; administer glucose (25 g as a 50% solution, IV) immediately after drawing blood for baseline values. Empiric glucose treatment will prevent hypoglycemic brain damage and outweighs the theoretical risks of additional harm to the brain in hyperglycemic, hyperosmolar, or anoxic coma. Thiamine (100 mg) must be administered with the glucose infusion to prevent precipitation of Wernicke encephalopathy in malnourished, thiamine-depleted patients. Rarely, an established thiamine deficiency can cause a coma.

Repeated generalized seizures damage the brain and *must be stopped*. Initial treatment should include IV benzodiazepines, lorazepam (2-4 mg), or diazepam (5-10 mg). Seizure control can be maintained with phenytoin (18 mg/kg IV at a rate of 25 mg/min) (also see Chapter 54). Seizure breakthrough requires additional benzodiazepines.

Careful and mild sedation should be given to the agitated, hyperactive patient to prevent self-injury. Sedation facilitates ventilator support and diagnostic procedures. Small doses of IV benzodiazepines, intramuscular haloperidol (1 mg as often as hourly until the desired effect), or morphine (2-4 mg IV) are appropriate.

Consider specific antidotes: Drug overdose is the largest single cause (30%) of coma in the emergency room. Most drug overdoses can be treated by supportive measures alone. However, certain antagonists specifically reverse the effects of coma-producing drugs. Naloxone (0.4-2 mg, IV) is the antidote for opiate coma. The reversal of narcotic effect, however, may precipitate acute withdrawal in an opiate addict. In a suspected opiate coma, the minimum amount of naloxone should be given to establish the diagnosis by pupillary dilatation and to reverse respiratory depression and coma. Do not attempt to completely reverse all drug effects with the first dose. IV flumazenil reverses all

benzodiazepine-induced coma, and a coma unresponsive to 5 mg flumazenil in divided doses given over 5 minutes is not due to a benzodiazepine overdose. Recurrent sedation can be prevented with flumazenil (1 mg IV) every 20 minutes.¹⁸ The sedative effects of drugs with anticholinergic properties, particularly tricyclic antidepressants, can be reversed with physostigmine (1-2 mg IV). Pretreatment with 0.5 mg atropine will prevent bradycardia. Only full awakening is characteristic of an anticholinergic drug overdose, as physostigmine has nonspecific arousal properties. Physostigmine has a short duration of action (45-60 minutes), and doses may need to be repeated.

Adjust body temperature: hyperthermia is dangerous because it increases the brain metabolic demand and, at extreme levels, denatures brain proteins.¹⁹ Hyperthermia above 40°C requires nonspecific cooling measures even before the underlying etiology is determined and treated. Hyperthermia most often indicates an infection but may be due to intracranial hemorrhage, anticholinergic drug intoxication, or heat exposure. A body temperature of below 34°C should be *slowly* increased to above 35°C to prevent cardiac dysrhythmia. Hypothermia accompanies profound sepsis, sedative-hypnotic drug overdose, drowning, hypoglycemia, or Wernicke encephalopathy.

History

Once vital functions have been protected and the patient's condition is stable, clues to the cause of the coma must be sought by interviewing relatives, friends, bystanders, or medical personnel who may have observed the patient before or during the decline in consciousness. The history should include:

- Witnessed events: Head injury (see Chapter 56), seizure, details of a motor vehicle accident, circumstances under which the patient was found.

- Evolution of a coma: Abrupt or gradual, headache, progressive or recurrent weakness, vertigo, nausea, and vomiting.
- Recent medical history: Surgical procedures, infections, and current medication.
- Past medical history: Epilepsy, head injury, drug or alcohol abuse, stroke, hypertension, diabetes, heart disease, cancer, and uremia.
- Previous psychiatric history: Depression, suicide attempts, and social stresses.
- Access to drugs: Sedatives, psychotropic drugs, narcotics, illicit drugs, drug paraphernalia, empty medicine bottles.

General Physical Examination

A systematic, detailed examination is helpful and necessary in the approach to the comatose patient, who is in no condition to describe prior or current medical problems. This examination is an extension of the rapid initial evaluation and should look for:

- Efficacy of resuscitation measures, determined by repeated assessment of vital signs.
- External evidence of trauma.
- Evidence of acute or chronic medical illnesses.
- Evidence of ingestion or self-administration of drugs (e.g., needle marks, alcohol on breath).
- Evidence of nuchal rigidity. Caution is required if severe neck injury is possible or has not been excluded. Nuchal rigidity may disappear in deeply comatose patients with meningeal infection/inflammation.

Neurologic Profile

Establishing the nature of the coma is critical for appropriate management and requires:

- Correct interpretation of neurologic signs that reflect either the integrity or impairment of various functional levels of the brain.
- Determining whether the pattern and evolution of these signs are best explained by a supratentorial or infratentorial structural lesion, a metabolic-toxic encephalopathy, or a psychiatric cause (Box 48-2 and Table 48-1).

The clinical neurologic functions that provide the most useful information in making a categorical diagnosis are outlined in Box 48-3. These indices are easily and quickly obtained. Furthermore, they have a high degree of interexaminer consistency, and when applied serially, they accurately reflect the patient's clinical course. Once the cause of coma can be assigned to one of these categories, specific radiographic, electrophysiologic, or chemical laboratory studies can be used to make a disease-specific diagnosis and detect existing or potential complications.

Specific Management**Supratentorial Mass Lesions**

If the cause of the coma is a presumed supratentorial mass, the severity and rate of evolution of signs should be determined. A stabilized patient next requires an emergency head CT or magnetic resonance imaging (MRI). Carotid angiography is less informative, and a skull x-ray is not helpful. The priority in a deep coma or established/threatening transtentorial herniation is to apply a medical treatment for intracranial hypertension successfully. Brief hyperventilation to a PaCO₂ between 25 and 30 mm Hg on an Fio₂ of 1.0 is the most rapid method to reduce intracranial hypertension. This is usually achieved by adjusting the ventilation rate to 10 to 16/min and tidal volume to 12 to 14 mL/kg. An osmotic agent must be given concurrently. The preferred osmotic agent is a 20% mannitol solution as a 1-g/kg body weight IV bolus. Maximum ICP reduction occurs within 20 to 60 minutes, and the effect of a single bolus lasts about 6 hours. Corticosteroids are not indicated in the emergent empirical management of increased ICP. Furthermore, since steroids are effective only for certain lesions (e.g., edema around a brain tumor or abscess), use can be delayed until a diagnosis has been made by a head CT. After the initial

ICP management, a head CT or MRI is required. The scan will reveal the nature of the supratentorial lesion and associated mass effect. Arrangements must be made to evacuate an epidural or subdural hematoma promptly. Intraparenchymal masses that acutely produce deep stupor or coma initially are best managed nonsurgically. When steroids are indicated, a dexamethasone bolus should be given (up to 100 mg IV), followed by 6 to 24 mg every 6 hours. Once signs of herniation have abated, the ventilator rate should be carefully reduced to achieve a $Paco_2$ of 34 to 37 mm Hg and additional ICP-induced therapy used to manage intracranial hypertension as necessary (see below).

The patient's vital signs and neurologic condition require repeated examination. The head should be kept slightly elevated (15 degrees). Mannitol may be repeated if necessary every 4 to 6 hours and/or hypertonic saline can be used either as bolus or infusion; serum electrolytes and fluid balance must be monitored. When patients with presumed increased ICP do not respond clinically as expected to medical management or when obstructive hydrocephalus complicates a supratentorial mass lesion, we favor the placement of a ventriculostomy into the lateral ventricle. The ventriculostomy allows for the accurate measurement of ICP and provides a method for CSF drainage if necessary (also see Chapter 56). The placement of a ventriculostomy

allows the calculation of CPP (mean systemic arterial pressure minus ICP), a critical determinant of CBF and therefore, of oxygen and substrate delivery. Monitoring ICP also allows for the titration of therapies. Drainage of CSF aims to reduce ICP to maintain CPP (>60 mm Hg) and improve intracranial compliance. After increased ICP has responded to emergency management and the patient's condition has stabilized, definitive treatment of the lesion mass is required as deemed appropriate.

Infratentorial Lesions

The evolution of neurologic symptoms and signs, as well as the neurologic exam, generally give sufficient information to localize the lesion to the posterior fossa; the lesions themselves may be intrinsic or extrinsic to the brainstem. Rapid neurologic deterioration of a patient suspected of harboring an infratentorial lesion can demand emergency treatment before a head CT scan is performed. Treatment of a presumed extrinsic compressive lesion of the brainstem entails measures that decrease ICP as outlined earlier. Patients in a stupor or showing signs of progressive brainstem compression from a cerebellar hemorrhage or infarction require urgent evacuation. Intrinsic brainstem lesions are best treated conservatively; an incomplete stroke may benefit from thrombolysis and/or heparin anticoagulation. Posterior

BOX 48-3 Characteristics of Categories of Coma**SUPRATENTORIAL MASS LESION AFFECTING DIENCEPHALON/BRAINSTEM**

Initial focal cerebral dysfunction
Dysfunction progresses rostral to caudal
Signs reflect dysfunction at one level
Signs often asymmetric

SUBTENTORIAL STRUCTURAL LESION

Symptoms of brainstem dysfunction or sudden-onset coma
Brainstem signs precede or accompany the coma
Cranial nerve and oculovestibular dysfunction
Early onset of abnormal respiratory patterns

METABOLIC-TOXIC COMA

Confusion or stupor precede motor signs
Motor signs usually symmetric
Pupil responses generally preserved
Myoclonus, asterixis, tremulousness, and generalized seizures common
Acid-base imbalance common, with compensatory ventilatory changes

PSYCHOGENIC COMA

Eyelids squeezed shut
Pupils reactive or dilated, unreactive (cycloplegics)
Oculocephalic reflex unpredictable, nystagmus on caloric tests
Motor tone normal or inconsistent
No pathologic reflexes
Awake-pattern EEG

fossa tumors are managed initially with osmotic agents and steroids; definitive treatment includes surgery and/or radiation. Placement of a ventricular catheter for acute hydrocephalus must be considered cautiously and in consultation with a neurosurgeon; the danger exists of potentially fatal upward transtentorial herniation.¹²

Metabolic Toxic Coma

The task of the physician in the first contact with the patient in a metabolic coma is to preserve and protect the brain from permanent damage. Metabolic and toxicologic studies must be performed on the first blood that is drawn (see Box 48-1). Treatable conditions that quickly, irreversibly damage the brain include the following.

Hypoglycemia. Glucose (50 mL of a 50% solution IV) should be given during emergency treatment before the blood results return. Prolonged hypoglycemic coma that has considerably damaged the brain will not be reversed by a glucose load; a glucose bolus may transiently worsen hyperglycemic hyperosmolar coma. In contrast, the osmolar load of IV glucose may transiently decrease the elevated ICP and lighten non-hypoglycemic coma. A glucose infusion is needed to prevent recurrent hypoglycemia.

Acid-Base Imbalance. The hyperventilating comatose patient with acute severe metabolic acidosis and threatening cardiovascular collapse requires emergency treatment. For an accurate assessment, an arterial blood gas measurement is mandatory. Administration of NaHCO₃ (1 mEq/kg body weight IV) can be life saving. Simultaneously, a search for and specific treatment of the cause must be conducted.

Hypoxia. Carbon monoxide poisoning requires hyperoxygenation with 100% oxygen to facilitate the excretion of this toxin. Closely monitor and correct blood pressure and cardiac rhythm abnormalities. Idiopathic and drug-induced methemoglobinemia is treated with methylene blue (1–2 mg/kg IV over a few minutes; repeat dose after 1 hour if needed). Anemia alone does not cause coma but exacerbates other forms of hypoxemia. Transfusion of packed red blood cells is appropriate for severe anemia (hematocrit < 25%). Cyanide poisoning causes histotoxic hypoxia of the brain. Treatment entails amyl nitrite (vapor or crushed ampule inhaled every minute), sodium nitrite (300 mg IV), followed by sodium thiosulfate (12.5 g IV).

Acute Bacterial Meningitis. A lumbar puncture must be considered in any unconscious patient with fever and/or signs of meningeal irritation. If possible, an emergency head CT should be performed before a lumbar puncture on a comatose patient to rule out unexpected mass lesions. Increased ICP is present in all cases of bacterial meningitis, but a lumbar puncture is not contraindicated when this diagnosis is suspected. Cerebral herniation seldom, if ever, occurs except in small children.²⁰ Clinical correlates of impending herniation demanding a more cautious approach to lumbar puncture including a coma or rapidly deteriorating level of arousal, focal neurologic signs, and tonic or prolonged seizures. Papilledema is rare in acute bacterial meningitis. Should unexpected herniation occur after a lumbar puncture, treatment with hyperventilation and IV mannitol is indicated. Appropriate antibiotic treatment can usually await the results of spinal fluid Gram stain. If the Gram stain is negative, yet a bacterial etiology is suspected, empiric broad-spectrum antibiotic treatment with a third-generation cephalosporin and vancomycin is appropriate.

Drug Overdose. Certain general principles apply to all patients suspected of having ingested sedatives.^{21,22} Most drug overdoses are treated by emergent and supportive measures (Table 48-2). Once vital signs are stable, attempts should be made to remove, neutralize, or reverse the effects of the drug. Patients in a coma from recent drug ingestion require gastric lavage after tracheal intubation. A large (preferably double-lumen) gastric tube must be placed orally. Lavage is performed in the head-down position on the left side, using a 200- to 300-mL bolus of tap water or 0.45% saline and continued until the return is clear. After lavage, 1 or 2 tablespoons of activated charcoal are passed down the lavage tube. With meticulous support, patients with uncomplicated drug-induced coma should recover without neurologic deficit. Hemodialysis can hasten the recovery from coma due to massive doses of barbiturates or glutethimide.

Constant vigilance and attention to the patient's condition, with timely and appropriate diagnostic and therapeutic evaluation, assures the best possible outcome of metabolic coma. Effective care demands meticulous attention to the maintenance of tissue perfusion and oxygenation, documentation, and the anticipation of acute neurologic events (particularly diminished cerebral perfusion, herniation, or seizures), aggressive, rapid treatment of initial or subsequent infections, and prevention of agitation. Deep venous thrombosis can be prevented with either subcutaneous heparin (5000 units every 12 hours) or full-length leg pneumatic compression boots. Enteral or parenteral feeding within 36 to 48 hours is required to satisfy nutritional needs. Corneal injury can be prevented by protecting the eyes with lubricants and taping the lids shut.

THE ROLE OF SPECIAL INVESTIGATIONS**Neurodiagnostic Imaging**

Once the patient with an altered mental status is resuscitated and stabilized, further investigation may be necessary to document the location and type of the lesion, as well as direct therapy. CT and MRI provide an anatomic and/or functional assessment of the CNS and helpful information for defining the localization of lesions that produce a coma.

A cranial CT scan is the most expedient imaging technique for evaluating the comatose patient and gives the most rapid information about possible structural lesions with the least risk. The value of CT in defining mass lesions, hemorrhage, and hydrocephalus is established. The CT scan shows tissue shifts due to intracranial intercompartmental pressure gradients, but compared to MRI may underestimate the anatomy of the herniation.¹¹ Certain lesions, such as early infarction (<12 hours' duration), encephalitis, and isodense subdural hemorrhage may be difficult to visualize. Posterior fossa pathology may be obscured by bone artifacts inherent in the CT technique. Raised ICP is suggested by effacement of cortical sulci, a narrow third ventricle, and obliteration of the suprasellar or quadrigeminal cisterns but cannot be otherwise quantified.

TABLE 48-2 Neurologic Manifestations of Common Drug Poisoning

| DRUG | SIGNS & SYMPTOMS | DIAGNOSTIC TEST | TREATMENT |
|--|---|--|--|
| Carbon monoxide | Confusion, agitation, headache, convulsions, coma, respiratory failure, cardiovascular collapse | History Carboxyhemoglobin level | Remove patient from area, 100% oxygen until carboxyhemoglobin levels fall to <5% Hyperbaric oxygen if central nervous system affected Treat cerebral edema with hyperventilation, diuretics, and cerebrospinal fluid drainage if necessary |
| Salicylate | Tinnitus, hyperpnea, confusion, convulsions, coma, hyperthermia | Blood | Supportive care, gastric lavage, charcoal, systemic alkalinization, hemodialysis for coma or seizures |
| Cyanide | Agitation, confusion, headache, vertigo, hypertension, hypotension, seizures, paralysis, apnea, coma | Blood | Amyl nitrate, sodium nitrate, sodium thiosulfate, 100% oxygen, hyperbaric oxygen for refractory signs Vitamin B ₁₂ injection |
| ANTICONVULSANTS | | | |
| Phenytoin | Drowsiness, ataxia, nystagmus, tremulousness, coma | Blood | Supportive care, gastric lavage, charcoal |
| Carbamazepine | Dysrhythmias with carbamazepine or phenytoin overdose | Ammonia level in patients taking valproic acid | Watch for withdrawal seizures |
| Phenobarbital (see barbiturates) | | | |
| Valproic acid | | | |
| Primidone | | | |
| Ethosuximide | | | |
| Felbamate | | | |
| Clonazepam (see benzodiazepines) | | | |
| SEDATIVE HYPNOTICS | | | |
| Benzodiazepines | Confusion, lethargy, ataxia, nystagmus, hypothermia, dysarthria, respiratory depression, coma | Blood | Supportive care, gastric lavage, flumazenil for benzodiazepine overdose, hemoperfusion for extreme barbiturate intoxication |
| Barbiturates | | | |
| Chloral hydrate | Pupillary reactions preserved except in instances of deep barbiturate coma | | |
| Meprobamate | Possible withdrawal seizures | | |
| Ethchlorvynol | Agitation, hypertonic hyperreflexia, ataxia, hallucinations, convulsions | Blood | As above |
| Methaqualone | | | |
| Ethanol | Confusion, agitation, delirium, ataxia, nystagmus, dysarthria, coma | Blood, breath | Supportive care, lavage if within 1 hour of ingestion, thiamine, glucose |
| Opioids | Lethargy, small reactive pupils, hypothermia, hypotension, urinary retention, shallow irregular respirations, convulsions | Urine Response to naloxone | Naloxone, 0.4 mg IV or IM; continuous naloxone infusion if necessary Supportive care with intubation as necessary Lavage if overdose is by ingestion |
| STIMULANTS | | | |
| Amphetamine | Hypervigilance, paranoia, violent behavior, tremulousness, dilated pupils, hyperthermia, tachycardia or arrhythmia, focal neurologic signs secondary to CNS stroke or hemorrhage, seizures | Blood, urine | Supportive care, sedation with benzodiazepines Treat hypertensive crisis with sodium nitroprusside or labetalol Watch for rhabdomyolysis |
| Methylphenidate | | | Gastric lavage, charcoal |
| Cocaine | | | Benzodiazepines and haloperidol for sedation |
| Psychedelics (e.g., LSD, mescaline, phencyclidine) | Delirium, delusions, marked agitation, hallucinations, hyperactivity, dilated pupils, hyperreflexia, nystagmus | Blood Measure phencyclidine levels in gastric juice | |
| ANTIDEPRESSANTS | | | |
| Tricyclic antidepressants | Anticholinergic effects: dry mouth, agitation, restlessness, ataxia, tachycardia or arrhythmias, hyperthermia, hysteria, convulsions, mydriasis | Blood, urine | Cardiac monitoring, gastric lavage, charcoal, mild systemic alkalinization Physostigmine for refractory arrhythmias Anticonvulsants for seizures Symptomatic care, gastric lavage, avoid narcotics |
| Monoamine oxidase inhibitors | Drowsiness, ataxia, seizures, hypertensive crisis Hypotension with severe overdose | | Gastric lavage |
| Neuroleptics | Dystonia, drowsiness, coma, convulsions, hypotension, miosis, tremor, hypothermia, neuroleptic malignant syndrome | Urine | Treat extrapyramidal signs with diphenhydramine or benztropine mesylate Treat neuroleptic malignant syndrome with dantrolene or bromocriptine |
| Lithium | Lethargy, tremulousness, weakness, polyuria, polydipsia, ataxia, seizures, coma | Blood | Hemodialysis for delirium, seizures, or coma |
| Methanol, ethylene glycol | Drunkness, hyperventilation, stupor, convulsions, coma | Blood | Symptomatic care, gastric lavage, ethanol infusion, hemodialysis |
| Antihistamines | Blindness with methanol use Anticholinergic effects: dry mucosa, flushed skin, hyperthermia, dilated pupils, delirium, hallucinations, seizures, coma | | For methanol intoxication, 4-methylpyrazole Supportive care, gastric lavage, control of seizures with benzodiazepines, physostigmine for life-threatening anticholinergic effects |
| Organophosphates | Cholinergic crisis: cramps, excessive secretions, diarrhea, bronchoconstriction Later: tremulousness, fasciculations, weakness, convulsions, hypertension, tachycardia, confusion, anxiety, coma | RBC cholinesterase level | Symptomatic care, decontamination, atropine, pralidoxime |

An MRI can be performed depending on the clinical setting and stability of the patient's condition. It is limited in the urgent setting of coma evaluation because of the length of time required to perform the imaging, image degradation can occur even by a slight movement of the patient, and the relative inaccessibility of the patient for emergencies that may occur during imaging. Nevertheless, an MRI provides superb visualization of posterior fossa structures, which is useful when intrinsic brainstem lesions are suspected as the cause of a coma.¹¹ MRI images of anatomic lesions (e.g., those resulting from acute stroke, encephalitis, central pontine myelinolysis, and TBI) are associated with a greater resolution and at an earlier time than CT scanning. Injection of gadolinium helps delineate the areas of blood-brain barrier breakdown and may augment the sensitivity of this technique. Moreover, diffusion imaging can almost immediately reveal ischemic brain. Sagittal MRI views are useful in documenting the degree of supratentorial or infratentorial herniations and may enable intervention before clinical deterioration (Fig. 48-1).¹¹ Newer MRI techniques allow functional imaging of the CNS by the measurement of CBF to a particular region. The future application of this technique may allow rapid determination of diminished CBF (e.g., in stroke or vasospasm) and may be useful in assessing the effect of therapeutic interventions.

Electroencephalogram

The EEG can provide useful information in the evaluation of the unresponsive patient. With metabolic and toxic disorders, EEG changes reflect the degree and severity of the altered arousal or delirium, characterized by decreased frequency of the background rhythm and the appearance of diffuse slow activity in the theta (4-7 Hz) and/or delta (1-3 Hz) range. Bilaterally synchronous and symmetric medium- to high-voltage broad triphasic waves are observed in various metabolic encephalopathies, most often in hepatic coma. Rapid beta activity (>13 Hz) suggests the ingestion of sedative hypnotics, such as barbiturates and benzodiazepines. Acute focally destructive lesions show focal slow activity. When periodic lateralized epileptiform discharges appear

acutely in one or both temporal lobes, herpes simplex encephalitis must be strongly considered. A nonreactive diffuse alpha pattern in a comatose patient usually implies a poor prognosis and is most often seen after anoxic insults to the brain or after acute destructive pontine tegmentum damage.^{23,24} A normally reactive EEG in an unresponsive patient suggests psychiatric disease, but a relatively normal EEG can accompany the locked-in syndrome, some examples of akinetic mutism, and catatonia, all of which can be caused by structural brain lesions. Attempts to correlate the pattern and frequency spectra of a post-resuscitative EEG with neurologic outcome have been unsatisfactory since its predictive value is at best 88% accurate.²⁵

Nonconvulsive generalized status epilepticus and repeated complex partial seizures may produce altered levels of awareness or arousal. Thus, the EEG is an indispensable tool for the diagnosis and management of both these disorders. Continuous EEG monitoring optimizes the management of status epilepticus, as clinical assessment is insufficiently sensitive to detect continued electrographic seizures. Furthermore, continuous EEG monitoring in the ICU has shown an unsuspected high incidence of electrographic seizure activity in critically ill neurologic patients.^{26,27}

Jugular Venous Oximetry

Changes in jugular venous oxygen saturation measures the relationship between cerebral metabolic rate and CBF.²⁸ This form of monitoring offers the potential to minimize secondary insults after traumatic brain injury (TBI) by providing a warning of cerebral ischemia. It should be considered in comatose patients in conjunction with ICP monitoring (discussed later) to optimize treatment.

Transcranial Doppler Ultrasonography

Transcranial Doppler ultrasonography allows for the noninvasive measurement of blood flow velocity in basal cerebral arteries.²⁹ The dynamic high resolution provided and confirmed correlation with

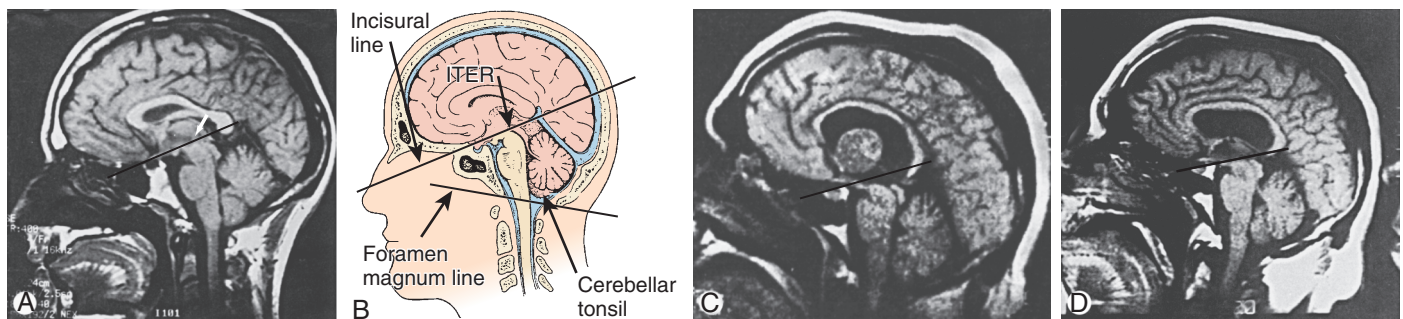

FIGURE 48-1 ■ Midsagittal magnetic resonance imaging (MRI) views of a normal adult brain and a brain with reversible downward transtentorial herniation. **A**, MRI view of the normal adult male brain. **B**, Schematic representation. The opening of tentorium of the cerebellum or anterior cerebellar notch lies along a line (incisural line) defined anteriorly by anterior tubercle of sella turcica and posteriorly by the junction of Galen's vein, inferior sagittal sinus, and the confluence of the straight sinus. The proximal opening of aqueduct of Sylvius, the iter ad infundibulum (*top arrow*), lies within 2 mm of incisural line. The foramen magnum line is defined between the inferior tip of clivus anteriorly and the bony base of posterior lip of the foramen magnum. **C**, A 47-year-old man who experienced 1 week of a headache, nausea, vomiting, and gait ataxia presented with an abrupt-onset coma, palsy of cranial nerve III, hyperreflexia, and bilateral extensor plantar responses. The MRI revealed third ventricular mass, obstructive hydrocephalus, and the displacement of iter ad infundibulum inferiorly by 6.5 mm. Cerebellar tonsils were not displaced. **D**, Subsequent MRI view in the same patient 2 weeks after surgical removal of a colloid cyst. Iter ad infundibulum is 1.2 mm below the incisural line. The patient had a full neurologic recovery. (**A**, **C**, and **D** from Reich JB, Sierra J, Camp W, et al. Magnetic resonance imaging measurements and clinical changes accompanying transtentorial and foramen magnum brain herniation. *Ann Neurol* 1993;33:159-70.)

other hemodynamic modalities encourages increasing numbers of neurointensivists to adopt the technique. Its importance in a coma is in the early detection of vasospasm in subarachnoid hemorrhage and at the time of brain death,³⁰ where an oscillating reverberatory movement has been noted in flow-velocity waveforms.

Evoked Potentials

Evoked potentials (EPs) are used to follow the level of CNS function in comatose patients.³¹ The clinical use of brainstem auditory evoked potential (BAEP) and short latency somatosensory evoked potential (SEP) responses stems from the correlation between EP waveform and presumed generators within certain CNS structures. The SEP shows special promise in the ICU field because EP components generated supratentorially in the thalamus and primary sensory cortex can be identified and followed over time. Shifts of intracranial structures that lead to herniation syndromes are reflected in abnormalities in SEPs, whereas BAEPs are generated entirely at or below the lower midbrain and are less often affected. EPs are less affected than EEG readings by sedatives and septic or metabolic encephalopathies, factors that often confound interpretations in comatose patients. Anatomic specificity and physiologic and metabolic immutability are the basis of clinical utility of EPs. Abnormal test results, however, are etiologically nonspecific and must be carefully integrated into the clinical situation by a physician familiar with their use. Caution is needed in the interpretation of SEPs to ensure that absent responses are not due to technical problems. Repeat SEPs are useful in the following progress. A progressive decline in response amplitude appears to be associated with a worsening prognosis. Studies have shown that all patients with anoxic coma and bilaterally absent SEPs had died or remained in the persistent vegetative state.³² In a traumatic coma, absent SEPs may be a less definitive prognostic indicator as recovery of consciousness has been reported in some patients.³³ Furthermore, comatose patients, especially those with the motor response of flexor posture or better, with an initial poor prognostic EEG pattern but normal SEPs, may have the potential for recovery and should be supported until their condition has changed to a more prognostically definitive category.³⁴ BAEPs and median SEPs obtained within 24 hours of coma onset had a 3-month predictive outcome (compared to Glasgow Outcome Scale [GOS]) in patients with TBI, brain hemorrhage, or neoplasm.³⁵ Diagnostic sensitivity for an unfavorable outcome was low for both parameters, although the specificity and positive predictive values were equally high for the abnormal wave VI of BAEPs and median SEPs.

Intracranial Pressure Monitoring

A review of published randomized controlled studies of real-time ICP monitoring by invasive or semi-invasive means in an acute coma (traumatic or nontraumatic etiology) versus no ICP monitoring (i.e., clinical assessment of ICP) examined the outcome measures of all-cause mortality and severe disability at the end of a given follow-up period.³⁶ The conclusion drawn is that there are insufficient data to clarify the role of routine ICP monitoring in all severe cases of acute coma. However, it is of value in TBI and should be considered on a case-by-case basis in other cases of coma.

Positron Emission Tomography

Recent studies comparing patients in a minimally conscious state and controls, using oxygen-15 positron emission tomography (PET), revealed activation patterns in key brain regions linked to pain processing that were distinguishable from patterns in patients in a persistent vegetative state. These observations suggest the need for analgesic treatment in a minimally conscious state but not for patients in the persistent vegetative state.³⁷ Additional use of brain PET as a research tool to study patients in comatose states will provide further important insight into this condition.

PROGNOSIS

A complete evaluation of the comatose patient must include an estimate of prognosis. The outcome in a given comatose patient cannot be predicted with absolute certainty. Available serial data are not sufficiently specific or selective to help in establishing the prognosis in an individual patient. Guidelines on the outcome of coma have been compiled based on serial examinations. Although the status of the comatose patient on admission is valuable in providing early informed discussion with relatives of patients and medical colleagues, that moment in most instances does not provide sufficient information to withhold immediate therapy. However, the early establishment of a highly probable poor outcome should ideally be made within 24 hours after hospital admission to protect families from false hope in futile cases. A logical and sensible approach to prognostication includes an etiologic subcategorization into a medical, drug-induced, and traumatic coma.

Numerous descriptive scoring systems, both pre- and in-hospital, are used in an attempt to assess the severity of the illness and predict patient outcome. A 2-year prospective study compared the severity-of-illness scoring systems (Acute Physiology and Chronic Health Evaluation [APACHE] II and Mainz Emergency Evaluation System [MEES]) to mental status measurement (Glasgow Coma Scale [GCS]) in predicting outcome of 286 consecutive adult patients hospitalized for nontraumatic coma.³⁸ There were no statistically significant differences among the scoring systems to correctly predict outcome. APACHE II and MEES should not replace GCS. For prediction of mortality, the GCS score also provides the best indicator in nontraumatic comatose patients (simple, less time consuming, and accurate in an emergency situations). Useful factors in determining the outcome of medical coma include cause, depth, and duration of coma. Clinical signs reflecting brainstem, motor, and verbal function are the most helpful and best validated predictors (95% confidence interval).³⁹⁻⁴² Overall, only 15% of patients in an established medical coma for 6 hours will make a good or moderate recovery; others will die (61%), remain vegetative (12%), or become permanently dependent on others for daily living (11%). Prognosis depends largely on the etiology of the medical coma. Patients in a coma due to a stroke, subarachnoid hemorrhage, or cardiorespiratory arrest have only about a 10% chance of achieving independent function. Some 35% of patients will achieve moderate to good recovery if the coma is due to other metabolic reasons including infection, organ failure, and biochemical disturbances. Almost all patients who reach the hospital after sedative overdose or other exogenous agents will recover moderately or completely. The depth of the coma affects individual prognosis. Patients who open their eyes in response to noxious stimuli after 6 hours of coma have a 20% chance of making a good recovery, versus 10% if eyes remain closed. The longer the coma persists, the less likely the chances for recovery; 15% of patients in a coma for 6 hours make a good or moderate recovery compared with only 3% who remain unconscious at 1 week.^{39,40} Coma following TBI has a somewhat better prognosis (see later discussion).

The severity of signs of brainstem dysfunction on admission inversely correlates with the chance of a good recovery from a medical coma. Absent pupillary responses at any time after onset and, except in barbiturate or phenytoin poisoning, absent caloric-vestibular reflexes 1 day after onset indicate a poor prognosis (<2% recovery). Except for sedative drug poisoning, no patient with absent pupillary light reflexes, corneal reflexes, oculocephalic or caloric responses, or lack of a motor response to noxious stimulation at 3 days after onset is likely to regain independent function. In a prospective study of 500 patients in a medical coma, a uniform group of 210 patients suffered anoxic injury: 52 had no pupillary reflex at 24 hours, all of whom died. By the third day, 70 were left with a motor response worse than withdrawal and all died. By the seventh day, the absence of roving eye movements was seen in 16 patients, all of whom died.^{39,40}

Patients likely to recover to functional independence will within 1 to 3 days speak words, open their eyes to noise, show nystagmus

on caloric testing, or have spontaneous eye movements. More than 25% of patients with an anoxic injury who show roving conjugate eye movements within 6 hours of the onset of coma or who show withdrawal responses to pain or eye opening to pain will recover independence and make a moderate or good recovery. The use of the combination of clinical signs helps to improve the accuracy of prognosis: at 24 hours, the absence of a corneal response, pupillary light reaction, or caloric or doll's-eye response is not compatible with recovery to independence.

Postanoxic convulsive status epilepticus and/or myoclonic status epilepticus reflect a poor prognosis. Occasionally, patients recover consciousness but remain handicapped; however, most die or become vegetative.^{43,44} Associated clinical findings (e.g., a loss of brainstem reflexes or eye opening at the onset of myoclonic jerks) and sinister EEG patterns (e.g., suppression or burst-suppression) confirm the grim neurologic outcome in this group. Autopsy studies show that cerebral and cerebellar damage can be ascribed to the initial ischemic hypoxic event; although there is no evidence that status epilepticus further contributes to this damage. Please see Chapter 54 for further details of therapy.

A meta-analysis of prognostic studies in anoxic-ischemic coma examined the value of biochemical markers of brain damage in CSF or serum.⁴⁵ Only levels of CSF markers (i.e., creatine kinase brain isoenzyme, neuron-specific enolase) reached the 0% false-positive rate. Since small numbers of patients are involved in studies and methodological limitations, the results are not sufficient to provide a solid basis for management decisions of patients in a coma.

The most accurate prediction of outcome in a patient in a medical coma is obtained from the use of a combination of clinical signs, and there is little to be added by more sophisticated testing, other than identifying the cause of the coma.^{39,40} Within the first week, it is hard to justify the withdrawal of therapy from patients in a medical coma unless they are already brain dead or lack all signs of brainstem function. After that, the probability of being able to predict the quality of life increases steadily. A multisociety task force of neurologists and neurosurgeons obtained a large amount of data concerning the persistent vegetative state that provides guidelines to outcomes in patients remaining vegetative 1 month following severe TBI or coma-producing medical illness (mostly anoxic).¹⁵

The recent and widespread application of mild therapeutic hypothermia after cardiac arrest has raised concern about the reduced or altered ability to prognosticate outcome. Clinical variables, such as brainstem reflex recovery, myoclonus, and absent motor response to pain, showed higher false-positive mortality predictions in comatose survivors of cardiac arrest compared to predictions by the American Academy of Neurology guidelines at 72 hours.⁴⁶ Greater use of higher doses of sedatives related to hypothermia therapy or the direct effects of hypothermia may play a role.^{47,48} Therefore, caution in prognostication is advised until a better understanding of the effects of this important new therapy emerges.

Among adults with TBI who were in a vegetative state at 1 month ($n = 434$), 33% died, 15% remained vegetative, and 28% suffered a severe disability at 1 year. Among children vegetative for 1 month post trauma ($n = 106$), 9% died, 29% remained in a persistent vegetative state, and 35% were severely disabled at 1 year; only 27% attained moderate/good recovery.

Nontraumatic (medical) coma results were even worse. Among 169 adults with nontraumatic brain injury who were vegetative at 1 month, 53% died within 1 year, 32% remained vegetative, and only 14% made a moderate/good recovery. The outcome of 45 children in similar circumstances was associated with 22% dead, 65% still vegetative, and only 6% with a moderate/good recovery at 1 year.

It is possible in a fraction of patients to predict within the first week those who will recover, those who will die in a coma or enter a vegetative state, and those who will survive with a severe disability. It is well established that patients in an anoxic coma who are in a vegetative state for 1 month will never recover their full preanoxic physical or cognitive function.

Patients in a coma due to exogenous agents (except carbon monoxide poisoning) carry an overall good prognosis, provided that circulation and respiration are protected by avoiding or correcting cardiac dysrhythmia, aspiration pneumonia, and respiratory arrest. Despite absent brainstem reflexes (i.e., electrocerebral silence on EEG), patients with deep sedative drug intoxication have the potential for a complete recovery. Therefore, in the emergent situation, patients in a coma of uncertain etiology should be supported vigorously until the precise cause of the coma has been fully established.

The outcome of a traumatic coma is better than a medical coma, and the prognostic criteria are somewhat different.^{15,33,49} Many patients with TBI are young; posttraumatic prolonged unconsciousness of up to several months does not always preclude a satisfactory outcome; and compared to the initial degree of neurologic abnormality, patients in a traumatic coma improve more than patients in medical coma. Patients in a coma for longer than 6 hours after TBI have a 40% chance to recover to moderate disability or better at 6 months. The most reliable predictors of outcome at 6 months are:

1. Patient age (worse outcome especially after 60 years).
2. Depth and duration of coma (an inverse correlation with GCS).
3. Pupil reaction and eye movements (absence at 24 hours predicts death or a vegetative state in 90%).
4. The motor response during the first week of injury (Table 48-3).

An independent poor prognostic indicator is sustained, uncontrollably increased ICP (>20 mm Hg). Additional factors play a role in the eventual outcome from a traumatic coma. Specific lesions (e.g., subdural hematoma) that result in a coma can have $<10\%$ recovery rate.⁵⁰ In studies with blunt trauma, comatose patients with increased plasma glucose, hypokalemia, or elevated blood leukocyte counts were associated with lower GCS scores and increased probability of death.⁵¹ There are some reports of patients who have suffered coma as a result of TBI in whom an improvement from the vegetative state has been recognized after months, but these anecdotal cases of recovery are difficult to validate. It seems possible that such patients were not truly vegetative but rather in a state of profound disability with minimal cognition at the beginning of observation.⁵² In one case report, however, patient

recovery from a 19-year-duration TBI-induced minimally conscious state was associated with improvements in white matter tracts, demonstrated with MRI diffusion tensor technique.⁵³ Novel MRI technology may thus aid in explaining these unusual recoveries; however, additional studies are warranted.

A systematic review of the trials reporting on multisensory stimulation programs in TBI patients in a coma or the vegetative state found no reliable evidence of the effectiveness of such techniques when compared to standard rehabilitation.⁵⁴ Outcome measures included the duration of unconsciousness (time between injury and response to verbal commands), the level of consciousness (GCS), the level of cognitive functioning, functional outcomes (GOS), or the disability rating scale. The overall methodologic quality was poor, and studies differed widely in design and conduct. Owing to the diversity in reporting of outcome measures, a meta-analysis was not possible. Continuous subcutaneous apomorphine infusion (to stimulate dopaminergic neurotransmission) has been suggested to facilitate awakening, specifically in a traumatic coma.⁵⁵ Consistent with this concept of dopaminergic stimulation, treatment with amantadine may also facilitate the emergence from a coma or states of profound disability after TBI as shown in a randomized trial.⁵⁶ Similarly, other work has suggested possible arousal effects from either a prolonged coma or minimally conscious state with zolpidem administration.⁵⁷ Therefore, further study is warranted.⁵⁸

Prognostic guidelines for medical and traumatic coma should be applied with care. One must be sure that the evaluation and interpretation of clinical signs are correct. The prognostic signs, however, predict general outcomes in large patient groups and cannot be applied with absolute precision to every individual comatose patient. One must selectively exclude the effects of anticholinergic agents (used during resuscitation) on pupillary reactivity and paralytic agents on the motor response.

The ability to predict prognosis following a coma can benefit the patient, family, and physician. Families can be spared both the emotional and financial burdens of caring for individuals with an insignificant chance of independent function and quality of life. Physicians can then properly allocate limited resources to patients with the potential to benefit from advanced medical care. There are recognized difficulties in interpreting outcome studies of coma prognosis: lack of prospective studies, failure to state confidence intervals, and the fact that patients in a coma may die of a nonneurologic disease. The self-fulfilling nature of a poor prognosis is difficult to eliminate: the care of a patient will reflect the treating physicians' impressions and opinions on patient outcome. Ideally, prognostic studies should only be performed on patients who will receive maximal life support for as long as possible, but this is inconsistent with the humane and sensitive management of patients and their relatives.

Analysis of the SUPPORT (Study to Understand the Prognoses and Preferences for Outcomes and Risks of Treatments) trial was used to estimate the cost-effectiveness of aggressive care for patients with non-traumatic coma.^{59,60} Patients with reversible metabolic causes of coma were excluded. The incremental cost-effectiveness was calculated for aggressive care versus withholding cardiopulmonary resuscitation and ventilatory support after day 3 of coma. The incremental cost-effectiveness of the more aggressive strategy was \$140,000 (1998 dollars) per quality-adjusted life year for high-risk patients and \$87,000 per quality-adjusted life year for low-risk patients (five risk factors were age older than 70 years, absent verbal response, absent withdrawal to pain, abnormal brainstem response, and serum creatinine > 1.5 mg/dL). From a purely economic standpoint, making earlier decisions to withhold life-sustaining treatments for patients with very poor prognoses may yield considerable cost savings. On moral and ethical

grounds, however, many physicians object to having to consider the cost factor when it comes to making treatment decisions for more or less sick patients. However, growing financial constraints now imposed on the medical community from the top down by politicians and the business culture may no longer afford such luxury, even in a country like the United States.

KEY POINTS

1. Altered arousal is due to an acute or subacute brain insult and reflects either diffuse and bilateral cerebral dysfunction, failure of the brainstem-thalamic ascending reticular activating system, or both.
2. Coma is not a permanent state. Patients who survive evolve through and into altered behavioral states that reflect various degrees of recovery.
3. Urgent steps are required to minimize additional brain damage, often before the cause of coma is definitely established.
4. The initial assessment must focus on vital signs to determine the appropriate resuscitation measures (Airway-Breathing-Circulation).
5. When the patient is stable, clues to the cause of coma must be sought from informative sources.
6. A systematic, detailed examination is necessary for the comatose patient, who is in no condition to describe the past or current medical history.
7. To determine the cause and evolution of coma, the correct interpretation of neurologic signs that reflect the integrity or impairment of brain functional levels is required.
8. Categorization of coma (supra- or infratentorial structural lesions, metabolic-toxic encephalopathy, or psychogenic unresponsiveness) is important in deciding the sequence of diagnostic and therapeutic steps that ensure the best possible patient outcome.
9. The CT scan is the most expedient imaging technique to provide rapid information about a structural brain lesion and its consequences.
10. Although the outcome of a comatose patient cannot be absolutely predicted, a highly probable poor prognosis should ideally be made within 24 hours after admission to direct the use of intensive care services and protect families from false hope.
11. As a rule, patients in a coma due to exogenous agents carry a favorable prognosis, and patients in posttraumatic coma fare better than a medical coma.
12. With the recent advent of mild hypothermia therapy after cardiac arrest, caution in prognostication is advised because compared to present published guidelines, clinical variables at 72 hours after arrest can show higher false-positive mortality predictors in treated comatose survivors.
13. Therapy with amantadine may afford benefit in some cases of traumatic coma.

ANNOTATED REFERENCES

- Plum F, Posner JB. The diagnosis of stupor and coma. Philadelphia: FA Davis; 1980.
This book is a convenient "one-stop" reference to stupor/coma. It is an excellent source of information about the pathophysiology and etiology of altered consciousness.
- Hund EF, Lehman-Horn F. Life-threatening hyperthermic syndromes. In: Hacke W. Neurocritical care. Berlin: Springer-Verlag; 1994. p. 888–896.
This textbook on neurocritical care gives concise access to causes and treatment of medical and neurologic coma. Easy-to-access topics are discussed in short, easy-to-read chapters with a short list of references.
- Synek VM. Prognostically important EEG coma patterns in diffuse anoxic and traumatic encephalopathies in adults. J Clin Neurophysiol 1988;5:161–174.
The EEG is often used by clinicians to help establish the cause and prognosis of stupor and coma. This article usefully categorized EEG patterns according to a severity scale that can be incorporated into the bedside evaluation of a patient with altered consciousness.

Biofluid-based biomarkers of brain injury have great potential for aiding in diagnostic, monitoring, and therapeutic applications in neurointensive care. Brain injury biomarkers such as neuron-specific enolase (NSE) have already demonstrated some prognostic utility in patients after cardiac arrest¹ and also have potential uses in a variety of intensive care unit (ICU)-relevant central nervous system (CNS) insults such as traumatic brain injury (TBI) and stroke. In this chapter we will use TBI as a prototype disease to demonstrate how brain injury biomarkers could complement conventional diagnostic and monitoring tools in ICU management.

BIOFLUID-BASED BIOMARKERS FOR DETECTING BRAIN INJURY IN THE ICU

A biomarker is defined as a “biologically based parameter that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.”^{1a} During brain injury, a variety of cellular changes can occur, including degeneration, protease activation, oxidative stress, and metabolic disturbances. These changes result in the shedding of specific proteins into the cerebrospinal fluid (CSF) or serum that can be identified and studied for their association with disease presence, outcome, and progression. These biofluid-based biomarkers reflect the earliest changes that occur in the cells before the evidence of injury appears on images. Therefore, the use of biomarkers could offer a rapid, noninvasive, and cost-effective tool for the diagnosis of brain injury and determination of the subsequent need for additional diagnostic testing, monitoring, or therapeutic intervention.

Most biofluid-based markers of CNS injury to date are proteins or protein fragments. In the content of basic research, several brain injury biomarkers including NSE, glial protein S-100 β , glial fibrillary acidic protein (GFAP), and myelin basic protein (MBP) have been shown to have great utility in TBI specifically. Alpha-II spectrin protein and its breakdown products (SBDPs) are potential biomarkers of necrosis and apoptosis following TBI. The cleaved form of the axonally located microtubule binding protein tau (c-tau) has been identified as a new biomarker in mouse and rat TBI models. In addition, inflammation markers such as neurofilament-H are promising axonal injury biomarkers of various forms of acute brain damage in experimental TBI models.

Proteomics is the large-scale study of proteins, particularly their structures and functions. This field includes the study of changes in protein expression patterns as related to diseases and environmental conditions. The search for biomarkers of TBI has been approached by integrating biofluid and tissue information. This new approach takes advantage of functional synergy between certain biofluids and tissues with the potential for clinically significant findings. Using differential neuroproteomic methods, a systematic assessment has successfully identified additional protein biomarkers for TBI, such as ubiquitin C terminal hydrolase-L1 (UCH-L1) and microtubule-associated protein 2 (MAP2), with relevant animal models.²

The application of basic scientific discoveries to the clinical setting remains a challenge. Systems biology—the computational and mathematical modeling of complex biological systems—is an approach to building a holistic, systematic, and unbiased understanding of the

structural and behavioral elements of biological networks. Translating these findings into the clinical, data-driven development cycle, data-mining steps for discovery, qualification, verification, and clinical validation are needed. Data mining techniques used in this field extend beyond the level of data collection data to an integrated scheme of animal modeling, instrumentation, and functional data analysis. In the context of TBI proteomics, systems biology tools can be incorporated in several ways to overcome many of the limitations of simple proteomics.³

Current Biomarker Candidates and Their Properties

Although no biomarkers are yet FDA-approved for clinical use, considerable research into protein biomarkers for TBI has produced several putative diagnostic and prognostic markers. Table 49-1 describes the most studied potential TBI biomarkers.

GFAP is an astrocyte-specific intermediate filament protein known as a marker of astrocyte activation. Eight different isoforms of this protein are expressed across numerous subsets of astrocytes. Measurements of GFAP and its breakdown products have provided promising data on injury pathways, focal versus diffuse injuries, and prediction of morbidity and mortality. GFAP was studied in both CSF and serum of patients with severe TBI.⁴⁻⁹ Serum GFAP levels in severe and moderate TBI with GCS <12 are associated with unfavorable outcome at 6 months.¹⁰ New ELISA for GFAP and its breakdown products detected both mild-moderate TBI¹¹ and the full spectrum of TBI (TRACK-TBI cohort)¹² in two independent studies. Similarly, Metting et al. demonstrated that serum GFAP was increased in patients with an abnormal CT after mild TBI.¹³ Another follow-up study using the TRACK-TBI cohort shows that the combination of UCH-L1 with GFAP/BDP further improves its diagnostic utility.¹⁴

UCH-L1 is a deubiquitinating enzyme highly expressed in neuronal cells. It is one of the few markers identified using proteomic methods. In addition, its high brain specificity and abundance in brain tissue make it an attractive candidate marker. CSF and serum UCH-L1 levels were found to be elevated in patients with severe TBI, correlating with the severity and outcome of injury.^{15,16} Increased levels of UCH-L1 post-TBI is proposed to be secondary to blood-brain barrier (BBB) dysfunction.¹⁷ Several other studies also report the detectability of UCH-L1 in blood following mild TBI and with UCH-L1 levels correlating with traditional clinical assessments.^{11,18} However, the utility of UCH-L1 in mTBI with respect to its sensitivity and specificity requires further clinical assessment.

Tau is an intracellular, microtubule-associated protein with a molecular mass of 48 to 67 kDa that is highly enriched in axons. TBI was found to cause the cleavage of tau protein, with elevated levels of c-tau in CSF and serum. c-tau possesses many desirable characteristics of a biochemical marker and is associated with both disruption of the BBB and postinjury cleavage of tau protein.¹⁹ Other studies from two groups have demonstrated the significance of Tau/c-tau in predicting outcome in severe TBI patients.^{20,21} Similarly, several studies report the utility of Tau or c-tau in the prediction of outcome in mTBI.^{22,23} However, other studies have reported the poor ability of tau protein to predict outcome and postconcussion syndrome in mTBI.²⁴ Recently, two ultra-sensitive assay platforms were developed to enable the robust detection

TABLE 49-1 Potential TBI Protein Biomarkers That Could Have Critical Care Utilities

| TBI PROTEIN BIOMARKER | FULL PROTEIN NAME | ORIGIN | HUMAN SEVERE TBI DATA | HUMAN MODERATE-MILD TBI OR CONCUSSION DATA |
|-------------------------------|--|--|-----------------------|--|
| GFAP (and BDPs) | Glial fibrillary acidic protein (and its breakdown products) | Glial injury | Yes | Yes |
| UCH-L1 | Ubiquitin C-terminal hydrolase-L1 | Neural injury | Yes | Yes |
| Tau (P-Tau) | Microtubule-associated Tau protein (phosphorylated Tau protein) | Axonal injury | Yes | Yes |
| S100b | S100b protein | Glia/BBB | Yes | Yes |
| SBDPs (SBDP150, 145, and 120) | α II-spectrin breakdown products of 150, 145, and 120 kDa | Axonal injury; brain cell necrosis-apoptosis | Yes | ? |
| MBP | Myelin basic protein | Demyelination | Yes | — |
| NSE | Neuron-specific enolase | Neural | Yes | — |
| NF-H, NF-L | Neurofilament protein-light and -heavy | Axonal | Yes | — |

The above list of markers is not exhaustive but reflects the current state of the art. Other possible markers include neurofilament proteins MAP2 (microtubule-associated protein 2A,2B), fatty acid binding protein-H (H-FABP), and BDNF (brain-derived neurotrophic factor) and autoantibodies to brain antigens. But more studies are required for further clinical utility verification and biomarker characterization.

of Tau (and a phosphorylated form of Tau) in serum from acute-phase TBI patients with various levels of TBI severity.²⁵

S100B is a glia-specific calcium-binding protein. Elevated *S100B* levels accurately reflect the presence of neuropathologic conditions including TBI or neurodegenerative diseases linked to astroglial injury. More important, *S100B* levels are reported to rise before any detectable changes in intracranial pressure, neuroimaging, or neurologic examination findings. *S100B* is considered a prognostic biomarker of BBB permeability and CNS injury. Several studies have reported that *S100B* protein might detect brain death after severe TBI.^{26,27} Another study showed that serum and urine levels of *S100B* after TBIs have prognostic significance for survival and disability.²⁸ A similar study on serum *S100B* measured 24 hours after injury reported that it predicts unfavorable outcome—that is, Glasgow Outcome Scale (GOS) score <4 or death at 3 months after injury in severe TBI patients.²⁹ *S100b* elevation has also been found after mTBI.³⁰ Although *S100β* remains promising as an adjunctive marker, the main limitation toward its use is the lack of specificity to brain trauma, especially given that *S100B* can be released by cells other than astrocytes.

α II-spectrin is a cytoskeletal protein enriched in neuronal axons and presynaptic terminals. *α II-spectrin breakdown products (SBDPs)* are produced by the breakdown of α II-spectrin by calpain and caspase, which are activated in the brain after TBI. SBDPs thus reflect axonal damage. SBDP150 and SBDP145 are indicative of calpain activation, often associated with acute necrotic neuronal cell death, while SBDP120 is generated by the action of caspase-3 and is associated with delayed apoptotic neuronal death. α II-spectrin has been studied primarily in the context of severe TBI. Elevation of SBDP150 and/or SBDP145 levels in CSF was reported as a possible outcome predictor in patients with severe TBI versus initial CT diagnosis with Marshall grade. SBDPs, especially CSF SBDP150, may be useful as a differential diagnostic biomarker for its ability to distinguish between focal and diffuse injury in the acute phase of TBI.^{31,32} Whereas α II-spectrin is present in various nucleated cells and most tissues, its high abundance and enrichment in brain and the fact that SBDPs are injury-generated make SBDPs potentially useful TBI biomarkers, especially in combination with other more brain-specific markers.

Myelin basic protein (MBP) is one of the most abundant proteins in white matter, composing 30% of the myelin protein. MBP is important in the myelination of nerves. As a constituent of the sheath, MBP is essential for normal myelination and axonal signal conduction. Several studies on severe TBI patients have reported that MBP levels could

track the occurrence of post-TBI hypoxia, predict the outcome, and prompt adequate treatment.^{7,33} Serum MBP is elevated in the majority of children with acute TBI, including well-appearing children with TBI from child abuse in whom the diagnosis might otherwise have been missed.³⁴ Most recently, a review by Kochanek et al. suggests that MBP is a potential biomarker for pediatric TBI.³⁵ Because TBI lacks clinical sensitivity, the interest in MBP as a biomarker for TBI is lower than that of *S100B*, NSE, and GFAP. One possible explanation for this lack of sensitivity is that MBP undergoes extensive fragmentation/degradation following TBI, thus complicating its robust detection by traditional sandwich ELISA.

NSE is a glycolytic enzyme that is present in central and peripheral neurons and neuroendocrine cells, with serum levels rising after cell injury. NSE is passively released into the extracellular space only under pathologic conditions during cell destruction. Acute post-TBI levels of NSE and MBP were correlated with outcome in children, particularly those under 4 years of age.^{36,37} In the setting of diffuse axonal injury in severe TBI, levels of NSE at 72 hours after injury have shown an association with unfavorable outcome.³⁸ However, in very early studies, serum or CSF NSE were considered of limited utility as markers of neuronal damage.^{39,40} A limitation of NSE is the occurrence of false-positive results that occur because NSE is also present at high levels in red blood cells.

Neurofilament (NF) proteins are the key intermediate filaments in neurons and a major component of the axonal cytoskeleton. The major neuronal filaments in the CNS are those assembled from NF triplet proteins: neurofilament light (NF-L; 61 kDa), medium (NF-M; 90 kDa), and heavy (NF-H; 115 kDa). Following TBI, calcium influx into the cell contributes to a cascade of events that activates calcineurin, a calcium-dependent phosphatase that dephosphorylates neurofilament side-arms, presumably contributing to axonal injury. Phosphorylated NF-H (pNF-H) was found to be elevated in the CSF of adult patients with severe TBI compared to controls.⁴¹ Similarly, hyperphosphorylated NF-H has also been shown to significantly correlate with neurologic deficit in severe TBI children.⁴² More recently, phosphorylated NF-H was shown to stratify lower grades of injury, with significant rises in pNF-H seen up to 3 days after mild TBI. pNF-H levels in CSF are also elevated in amateur boxers. Although pNF-H is showing promise as both a sensitive and specific marker of axonal injury after TBI, consideration of other NF isoforms is needed to stratify injury severity in TBI patients. For example, amateur boxers also have elevated CSF levels of NF-L.²³

TBI is a complex injury: primary injury occurs at the moment of trauma, when tissues and blood vessels are stretched, compressed, and torn; secondary injury then follows. Secondary injury events include damage to the BBB, release of factors that cause inflammation, free radical overload, excessive release of the neurotransmitter glutamate (excitotoxicity), influx of calcium and sodium ions into neurons, and dysfunction of mitochondria. We thus anticipate a growing list of putative TBI biomarkers with different cell or subcellular origins and different diagnostic and prognostic properties. Such findings are also very likely for other relevant CNS insults in neurocritical care. Preclinical and clinical studies suggest the potential alteration of the following proteins in some cases of TBI: neurite degeneration markers, MAP2, amyloid β peptide (A β 1-40, A β 1-42), neuroinflammatory markers (microglial ionized calcium-binding adapter molecule 1, inflammatory proteins-caspase-1, NALP-1, ACS),^{43,44} biofluid levels of neurotropic markers (brain-derived neurotrophic factor, nerve and growth factor, and heart-type fatty acid binding protein).⁴⁵⁻⁴⁷ Last, autoimmune markers (autoantibodies to brain antigens such as GFAP) have also been reported as potential biomarkers for subacute or chronic phases of TBI.⁴⁸ However, future work is required for their clinical utility verification and biomarker characterization.

POTENTIAL USES OF BRAIN BIOMARKERS FOR TBI PATIENT MANAGEMENT

Severe TBI

TBI severity is assessed immediately or serially monitored using GCS cranial CT scan, which is also useful for identifying hemorrhage, swelling, or skull fracture. CT scans can also provide direct localization information that helps guide possible surgical intervention. Lesions contributing to increased intracranial pressure or intracranial hemorrhage frequently require decompressive craniectomy, ventriculostomy, or treatment to increase cerebral perfusion pressure with the objective of restoring energy and oxygen supply. During the acute phase of severe

TBI, protein biomarkers are thought to be released into the CSF and/or into the circulation by passing through the disrupted BBB. These body fluid-based biomarkers represent the extent of damage to neurons or astrocytes and reflect a great diversity in outcomes, ranging from immediate death to full recovery. Thus far, no single protein biomarker can describe the complete profile of TBI pathology, which involves a complex cascade of pathophysiologic events, subsequent degeneration of various brain cell types (neurons, glia, oligodendrocytes), and deterioration of brain micro- and macro-structures and functions. Brain function relies not only on intact neurons and astrocytes but also on intact network connectivity. Thus, ideally, we should use a combination of complementary TBI biomarkers that originate from different cell types or subcellular structures that are vulnerable to TBI (see Table 49-1). This approach will likely allow us to assess the extent of cellular and structural damage and, eventually, the recovery process of the brain as a whole at different stages after the initial TBI event (Fig. 49-1). Thus, by serial monitoring of biofluid levels (CSF, blood) for a panel of protein biomarkers, we can gain information regarding the severity of the injury, the progression of the injury, possible occurrence of secondary insult, and prognosis of TBI patients and may even be able to formulate personalized therapeutic strategies (Fig. 49-2).

In conclusion, we have described the importance of biofluid-based protein biomarker detection following severe TBI germane to neurocritical care. We also propose a possible logistic workflow where such TBI biomarkers tests can be integrated into common clinical practice for acute TBI patients in the critical care setting. We also covered a number of TBI protein biomarkers with potential uses in TBI. However, a limitation at present is the lack of an established point-of-care device (POC platform) that can readily provide biomarker readouts within 20 to 30 minutes. Another challenge is to determine whether we already have the optimal biomarkers for formulating the best possible biomarker panel for TBI or if we need to continue to search for more ideal candidates. The next 5 to 10 years promise to be an exciting time for witnessing how the implementation of TBI biomarker-based diagnostics will change medical practice regarding critical care TBI patient management and, ultimately, for the full spectrum of patients in the neurocritical care setting.

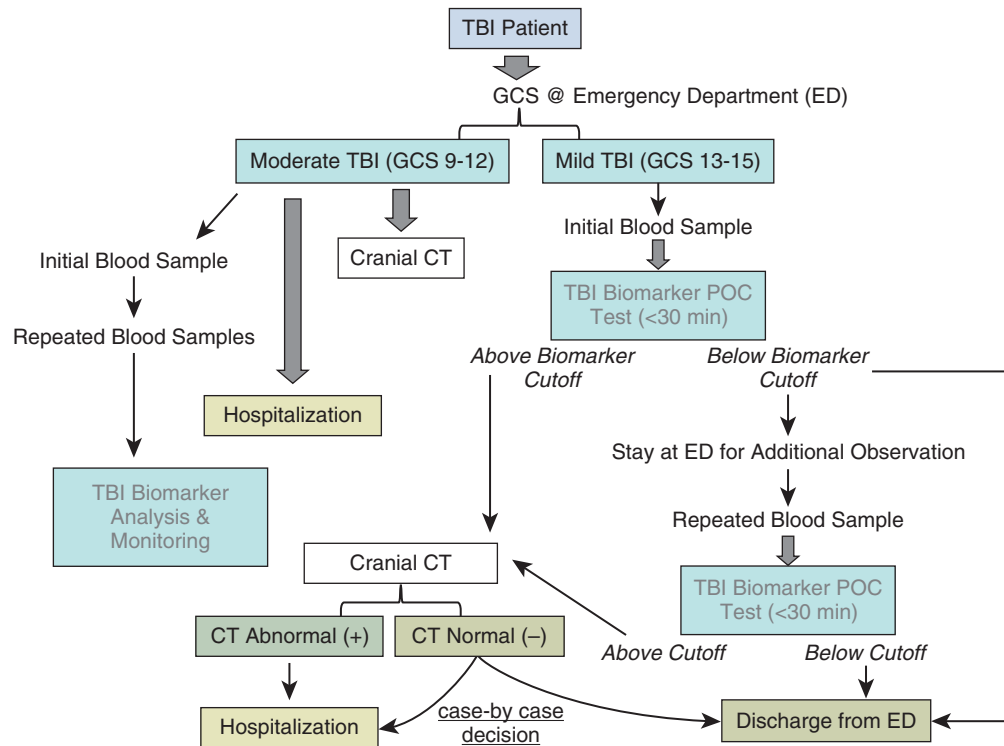

FIGURE 49-2 ■ Envisioned uses of brain biomarkers for mild-moderate traumatic brain injury (TBI) patient management.

KEY POINTS

1. Serum biomarkers of brain injury are being developed for multiple purposes and applications in a wide variety of patients in the neurocritical care setting including (a) prognostication, (b) to categorize injury severity, (c) to help identify otherwise unrecognized brain injury in ICU patients, and (d) to monitor treatment effects.
2. Glial fibrillary acidic protein (GFAP) is a marker of brain injury derived from astrocytes and is showing promise for clinical translation.
3. Two neuronal markers, namely ubiquitin C terminal hydrolase-L1 (UCH-L1) and neuron-specific enolase (NSE), also have potential to identify brain injury. NSE is currently used in some centers for prognostication after cardiac arrest.
4. Myelin basic protein is an emerging marker of white matter damage that is being assessed in clinical studies.
5. The microtubule associated protein Tau is an emerging biomarker that is implicated as an initiator of chronic neurodegenerative disease including chronic traumatic encephalopathy.

Cardiopulmonary arrest may occur as the endpoint or consequence of many diseases. Often when treatment is initiated the mechanism is unknown, and an algorithmic approach titrated to real-time monitoring is used. When the cause is known or suspected, therapy can be individualized and directed at that cause. In all cases, management has two priorities: (1) rapid restoration of cardiopulmonary function and (2) minimization of ischemic damage to end organs, especially the brain. Restoration of circulation is comprised largely of mechanical and electrical treatment. In contrast, treatment of brain and other organ injury primarily involves prevention of secondary cellular and molecular events using specific and detailed intensive care. Meaningful survival is unlikely without attention to both the heart and brain.

From the first introduction of closed-chest compressions until 2000, there was little change in long-term survival after cardiac arrest.^{1,2} However, subsequent regional efforts to improve resuscitation practices at multiple levels, including emergency response and post-cardiac arrest care, have yielded significant improvements in meaningful survival.^{3,4} Specific patterns of physiologic changes after cardiac arrest have been described, and there is accumulating evidence about which aspects of post-cardiac arrest management influence final outcomes.⁵⁻⁷ Improving outcomes further requires an integrated approach to immediate resuscitation, subsequent intensive care management, and post-intensive care recovery. This chapter will review the epidemiology of cardiac arrest, the initial approach for reversing cardiopulmonary arrest, modifications of this approach appropriate for specific disease states, and post-cardiac arrest care designed to minimize brain injury.

■ EPIDEMIOLOGY

In industrialized countries, heart disease is the overall leading cause of death, with an incidence of cardiopulmonary arrest outside the hospital ranging from 55 to 120 events per 100,000 people per year.⁸⁻¹¹ Median survival after out-of-hospital cardiac arrest is estimated at 10.6%,⁸ but the range varies regionally from less than 2%^{12,13} to 16% in certain exemplary systems.¹¹ The incidence of cardiac arrest in hospitals is about 0.17 events per hospital bed per year.¹⁴ For inpatients experiencing cardiac arrest, median survival to hospital discharge is about 20%.¹⁵ Almost half of in-hospital cardiac arrests occur in an intensive care unit (ICU) setting, where survival is higher than that in an unmonitored unit.¹⁵ Respiratory insufficiency is the most common preexisting condition for in-hospital cardiac arrest,¹⁵ and as many as 17% of episodes of respiratory compromise in hospitals progress to cardiac arrest.¹⁶

While out-of-hospital cardiac arrest is more common in men than in women both outside¹⁰ and inside hospitals,¹⁴ the incidence of cardiac arrest is higher in women (6%) than in men (4.4%) who are admitted to a hospital for acute myocardial infarction (MI).¹⁷ Cardiac arrest outside a hospital affects Blacks and Latinos more than Whites Caucasians or Asians,^{10,12,18} and rates are higher in neighborhoods composed of minority and lower socioeconomic status populations. These groups are also more likely to have a cardiac arrest, less likely to have bystander CPR, and less likely to survive.^{19,20} While sudden death can affect patients of all ages, the mean age for sudden cardiac arrest is between 65 and 70 years in most studies.^{10,11,14}

Most mortality after cardiac arrest is attributable to cardiopulmonary collapse or brain injury. Only one-third to one-half of patients who collapse outside a hospital and only 44% of patients who collapse in a hospital have restoration of circulation long enough to be admitted to the ICU.¹⁴ Two-thirds of patients who are admitted to a hospital after an out-of-hospital collapse²¹ and 60% of patients who are resuscitated from cardiac arrest in a hospital¹⁴ die prior to discharge from the hospital. Postischemic brain injury is the most common reason for in-hospital death after out-of-hospital cardiac arrest,^{14,22} whereas multiple organ failure is more common after in-hospital cardiac arrest.²³ Failure to awaken contributes to withdrawal of life-sustaining treatment for about 61% of out-of-hospital cardiac arrest patients.

■ RESTORING CIRCULATION

Acute treatment of cardiac arrest consists of two concurrent, goal-directed activities: (1) artificial circulation of oxygenated blood to heart and brain and (2) electric shock to terminate ventricular fibrillation (VF) and unstable tachydysrhythmias (Fig. 50-1). Continuous, uninterrupted, high-quality chest compressions are the cornerstone of resuscitation,²⁴ whereas electrical rescue shocks are used only when appropriate.²⁵ The organization of an electrocardiogram (ECG) and the presence of a pulse will prompt appropriate selection of therapy. The recommended division of time and prioritization of activities to accomplish these goals is depicted in Figure 50-2. All other activities, including medications and advanced airway maneuvers, are designed to supplement these two core activities, and optimization requires minimal interruption in the two core activities. Focused bedside ultrasound can aid in the assessment of critically ill patients and identify reversible causes only if performed without interrupting resuscitation.²⁶ The American Heart Association and European Resuscitation Council provide consensus scientific statements about the acute management of cardiac arrest, including a detailed review of specific drugs and procedures.²⁷ The following section provides an overview of airway management, circulation support, rescue shock for defibrillation, and drug therapy.

Airway and Ventilation

Obstruction of the airway occurs in patients with impaired consciousness, including cardiac arrest preventing oxygenation and ventilation.²⁸ Agonal respiration occurs after acute cardiac arrest for an additional 1 to 2 minutes,²⁹ which may confuse lay people and delay the recognition of cardiac arrest. While associated with survival, it is unclear whether agonal respiration generates sufficient ventilation to support life.³⁰ Regardless, artificial ventilation is required for patients requiring more than momentary resuscitation efforts.

Simple maneuvers to open the airway include extension of the neck (head tilt) and forward displacement of the mandible (chin lift). Insertion of an oropharyngeal or nasopharyngeal airway can displace the tongue from the posterior pharynx. Positive pressure ventilation using mouth-to-mouth or bag-valve-mask (BVM) ventilation with as little as 400 mL in adults (6-7 mL/kg) delivered over 2 to 3 seconds will cause the chest to rise.³¹ Minute ventilations smaller than those required for long-term support probably provide adequate gas exchange during cardiac arrest. Conversely, hyperventilation or hyperexpansion of

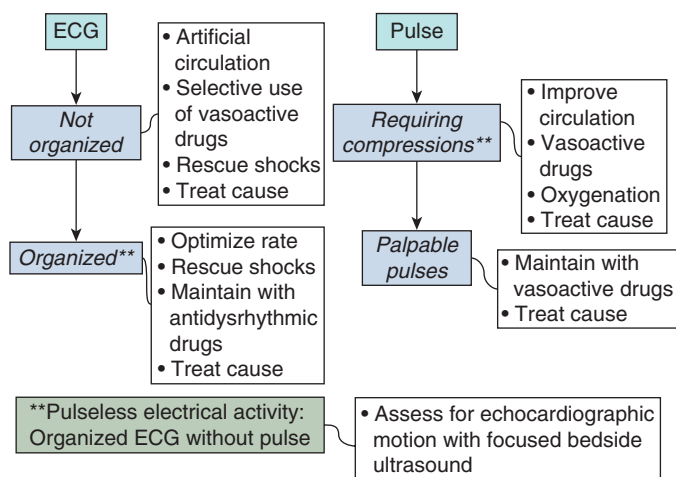

FIGURE 50-1 ■ Continuous reassessment of the patient during cardiac resuscitation relies on an ECG and on the presence of cardiac mechanical activity (pulses). If an organized ECG is not present, interventions should be undertaken to restore an organized ECG. If mechanical cardiac activity is not present, interventions should be undertaken to improve mechanical cardiac activity. Achieving both goals results in return of circulation.

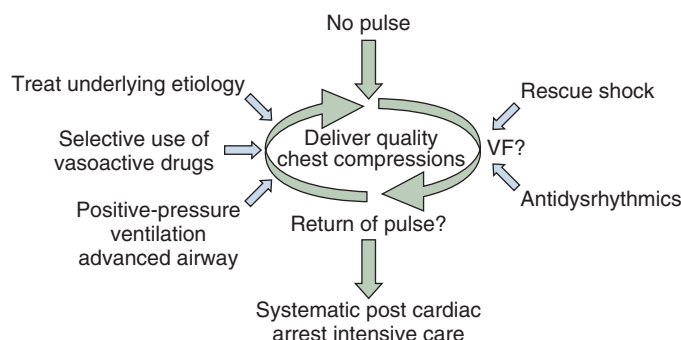

FIGURE 50-2 ■ Prioritization of activities must occur during cardiac resuscitation. Central circle emphasizes that core activity of chest compression should be interrupted only to provide rescue shocks when appropriate or when restoration of circulation occurs. All drugs, airway devices, and other interventions are designed to augment either artificial circulation or defibrillation. None of these adjuncts should interrupt or detract from providing artificial circulation. VF, ventricular fibrillation.

the chest impairs venous return and decreases circulation during resuscitation.³²

The need for gas exchange must be balanced against the fact that even brief interruptions in chest compressions reduces coronary perfusion pressure (CPP) (Fig. 50-3).³³ In swines, comparison of different chest compressions to ventilation ratios suggests that 2 breaths per 50 or more chest compressions are optimal for resuscitation.³⁴ An innovative practice to reduce interruptions in compressions is to provide chest compressions without any artificial ventilation³⁵ or with passive insufflation of oxygen.³⁶ Chest compressions alone probably do not generate significant ventilation in humans.^{28,37} As a compromise, some systems deliver uninterrupted chest compressions and asynchronous positive pressure breaths. Regardless of ratio, the duration of any pause to deliver breaths must be minimized.

Waveform capnography can confirm ventilation and monitor adequacy of circulation. During cardiac arrest, end-tidal CO₂ is related to

FIGURE 50-3 ■ Chest compressions provide coronary perfusion by creating a pressure gradient between the aorta (Ao) and the inside of ventricles (approximated by right atrium [RA]). Gradient between sites is the coronary perfusion pressure (CPP). During chest compression, pressure increases in both Ao and RA. During relaxation, pressure persists in Ao more than RA. Thus, myocardial blood flow is most related to CPP during relaxation phase of chest compressions. Note that CPP declines within 1 to 2 seconds when compressions pause for ventilation. (Unpublished laboratory data.)

cardiac output and pulmonary blood flow.³⁸ Therefore, CO₂ levels may be very low (<10 mm Hg) at the onset of resuscitation. Adequate artificial circulation will cause CO₂ levels to increase, and these levels may be used as a feedback to improve or modify chest compressions. An end-tidal CO₂ level greater than 15 to 16 mm Hg is associated with successful cardiac resuscitation.^{39,40} Conversely, end-tidal CO₂ less than 10 mm Hg after 20 minutes of resuscitative efforts can confirm failure of resuscitation.⁴¹ Common resuscitation drugs disrupt the association between capnography readings and pulmonary blood flow: epinephrine infusion reduces CO₂ levels, and sodium bicarbonate infusion produces a transient elevation of CO₂ levels. An abrupt increase in end-tidal CO₂ levels, usually to levels over 35 mm Hg, may be useful in recognizing the return of circulation, without interrupting chest compressions for pulse checks (Fig. 50-4).

Airway Devices

The most common ventilation device used by rescue personnel, paramedics, and other healthcare providers is a self-inflating bag attached to a face mask (BVM), which requires adequate training and practice for ventilation success by a single provider. Two providers achieve more reliable airway management. BVM ventilation also pushes air into the stomach.⁴² This can promote emesis and abdominal distention, impair venous return, and reduce lung compliance.⁴³ Normal esophageal resistance to air entry into the stomach (15 to 20 cm H₂O)⁴⁴ declines with loss of muscle tone during cardiac arrest (5–8 cm H₂O).⁴⁵

Tracheal intubation with a cuffed tracheal tube secures the airway definitively and protects from emesis. However, laryngoscopy requires an interruption in chest compressions. Observational studies found

FIGURE 50-4 ■ End-tidal CO₂ changes during resuscitation. Tracings from monitor-defibrillator with an accelerometer to measure chest compression depth (*top trace*) and waveform capnography to measure exhaled CO₂ (*bottom trace*). Exhaled CO₂ confirms correct placement of an advanced airway. Note frequent interruptions in chest compressions prior to placing advanced airway. More continuous chest compressions are followed by an abrupt rise in exhaled CO₂, corresponding to return of circulation, including pulmonary circulation. Chest compressions continue for 2 to 3 minutes until providers detect a palpable pulse.

extremely long interruptions in chest compressions during “uncomplicated” tracheal intubation.⁴⁶ Therefore, consider delaying tracheal intubation until after other life-saving interventions. Ultimately, patients in coma or with continued respiratory failure will require tracheal intubation.

Supraglottic airway adjuncts such as double-lumen combination tracheal-esophageal tubes (e.g., Combitube), laryngeal tubes (e.g., King-LT), or laryngeal mask airways can temporarily secure the airway during resuscitation.^{47,48} These devices have the advantage of blind insertion within seconds without laryngoscopy or interruptions in chest compressions.⁴² Clinicians should strongly consider using these supraglottic airways as the first advanced airway during resuscitation.

Artificial Circulation

In patients without a pulse, compression of the heart and chest by repetitive depression and release of the sternum circulates blood. The critical parameter for restoring myocardial energy stores and thus spontaneous circulation is the development of adequate CPP. CPP is the pressure gradient between the aorta and the inside of the ventricles at the end of diastole or during the relaxation phase of chest compressions. Most blood flows through the ventricular walls during diastole or during the relaxation phase of chest compressions, when ventricular pressure is the lowest (see Fig. 50-3). CPP is highly correlated with myocardial perfusion and consequently with the likelihood of resuscitation.⁴⁹ In humans, return of circulation requires that the developed CPP exceeds 15 to 20 mm Hg.

Peak arterial pressure or palpable pulses measured during chest compressions do not necessarily represent CPP because ventricular pressures are simultaneously elevated. Consequently, palpation of pulses and systolic pressures developed by chest compressions may be misleading. It is most useful to follow the “diastolic” or relaxation-phase arterial pressure. If unable to follow any of these pressures, the clinician must rely on indirect evidence of myocardial perfusion, such as improved electrical and mechanical activity or increased pulmonary CO₂ excretion.

Even brief interruptions in chest compressions decrease CPP, and interruptions are inversely associated with restoring circulation and survival.²⁴ When chest compressions are measured during actual resuscitations by paramedics or hospital providers, interruptions and

pauses are frequent.^{50,51} Some monitor-defibrillators now have features to measure and record chest compressions and to provide real-time feedback about depth and rate to providers.⁵² These features have no detectable effect on survival.⁵³ The chest compression fraction is one metric of compression continuity that is emphasized as a component of high-quality resuscitation²⁴ (Fig. 50-5), and many clinicians feel that the real-time and automated feedback is a useful safety and quality improvement mechanism to enhance total system performance.

Direct cardiac compression via thoracotomy is more effective than external chest compressions, producing roughly a three-fold increase in CPP.^{54,55} This approach also allows recognition of cardiac tamponade, treatment by pericardiectomy, direct visualization of mechanical activity and fibrillation, and direct electrical defibrillation or pacing. In the setting of cardiopulmonary collapse due to exsanguination, thoracotomy also allows for aortic compression to shunt blood to the heart and brain as well as direct control of intrathoracic bleeding. Until the 1960s, thoracotomy was the standard approach for treatment of sudden cardiac arrest, but this procedure has now been supplanted by closed-chest compressions. A cases series has described how this technique continues to be successful, and its use should be considered when closed-chest compressions are ineffective.⁵⁴ Open-chest cardiac massage is most likely to succeed if initiated early during resuscitation.⁵⁶

To improve delivery of uninterrupted chest compressions, a variety of mechanical devices have been developed.^{24,33,57,58,59} Some of these devices exploit circumferential compression or active compression/decompression of the chest. A Cochrane Review of mechanical versus manual chest compressions for cardiac arrest found no evidence of benefit of mechanical compressions in the return of spontaneous circulation or survival to hospital admission, and a subsequent pragmatic randomized trial found no improvement in 30-day survival.^{59,60} While no current device is superior to well-conducted manual compressions, these devices may play a role in providing chest compressions in settings where manual compressions are difficult or impossible (e.g., during ambulance transport, under the fluoroscopy arm, or when multiple providers are not available).

Extracorporeal Circulation

Extracorporeal perfusion for restoration of circulation (E-CPR) can be used to resuscitate subjects for whom chest compressions have

FIGURE 50-5 ■ Chest compression fraction (CCF) describes the continuity of chest compressions during resuscitation. Tracings of chest compressions detected by the accelerometer of a monitor-defibrillator can be used to calculate the proportion of time when chest compressions are occurring. In top tracing, there are few pauses, and CCF is 0.90. In lower tracing, frequent interruptions for breaths or procedures results in CCF of 0.60.

TABLE 50-1 Sample Selection Criteria for Extracorporeal Perfusion for Restoration of Circulation (E-CPR)

| | SURUGADAI NIHON UNIVERSITY HOSPITAL TOKYO, JAPAN | SHARP MEMORIAL HOSPITAL SAN DIEGO, CA | ALFRED HOSPITAL MELBOURNE, VICTORIA, AUSTRALIA |
|-------------------------------|--|--|--|
| INCLUSION CRITERIA | Age 18 to 74 Witnessed cardiac arrest Presumed cardiac etiology EMS arrival ≤15 minutes Defibrillation by AED or EMS personnel Persistent cardiac arrest on arrival to ED | Persistent cardiac arrest Shock refractory to standard therapies | Age 18 to 65 Suspected cardiac etiology Any CPR within 10 minutes of collapse Initial rhythm of ventricular fibrillation 30 minutes of persistent cardiac arrest |
| EXCLUSION CRITERIA | Presumed noncardiac etiology Successful ROSC ≤10 minutes of arrival to ED Core body temperature <30°C on arrival to ED Pregnancy | Initial rhythm of asystole Any CPR not initiated ≤10 minutes of cardiac arrest Estimated EMS transport time >10 minutes Total arrest time >60 minutes Suspicion of sepsis or hemorrhage Preexisting severe neurologic disease | Known preexisting significant neurologic disability Known significant end-stage comorbidities Terminal illness due to malignancy |

AED, automatic external defibrillator; ED, emergency department; ROSC, return of spontaneous circulation.

failed.^{61,62,63} However, this approach requires specialized technical skill, system commitment, and increased costs and risks. Logistical issues include limited availability of perfusion equipment, setup time for circuit priming, and delays in establishing adequate venous and arterial access. Portable cardiopulmonary bypass devices that can be primed quickly, along with improved techniques for rapid vascular access, have broadened the use of E-CPR.

It is critical that E-CPR be used for appropriately selected patients. The ideal candidate is young with a witnessed cardiac arrest from a shockable rhythm, with a presumed cardiac etiology, who receives immediate CPR, and who has a brief interval until successful

cannulation and commencement of extracorporeal resuscitation. Examples of selection criteria from three centers are given in Table 50-1.

The timing of E-CPR is equally important because irreversible myocardial and neurologic injury can preclude survival despite restoring flow. Conventional resuscitation is clearly preferred when patients have early recognition, early high-quality chest compressions, and early defibrillation. However, increasing the duration of treated cardiac arrest decreases the odds of functionally favorable survival (perhaps as low as 1% after 16 minutes of professional resuscitation).⁶⁴ After failing rapid resuscitation, E-CPR should be considered for suitable

candidates. One successful E-CPR program found that 85% of E-CPR survivors had perfusion started less than 55 minutes after collapse. Longer initiation times were rarely associated with favorable neurologic recovery.⁵⁸

Electrocardiogram Monitoring

Continuous three-lead ECG monitoring is essential for guiding resuscitation. A practical approach is to divide rhythms into organized and not organized. Organized rhythms include supraventricular rhythms or ventricular tachycardia (VT). Not-organized rhythms include VF and asystole. Not-organized rhythms cannot support the pumping of blood, regardless of volume status, cardiac muscle state, and vascular integrity. Therefore, restoring cardiac electrical activity to an organized rhythm is an essential step in resuscitation. Organized rhythms can support pumping of blood unless they are too slow (<30-40 complexes/min) or too fast (>170-180 complexes/min). An organized rhythm in the absence of a pulse is termed *pulseless electrical activity* (PEA).

As the incidence of PEA as initial cardiac rhythm increases, with a relative decrease in the incidence of initial VF,^{10,65-67} PEA is an area of increased study and focus. Point-of-care cardiac ultrasound during resuscitation allows for more nuanced assessment of PEA. PEA may be subdivided into an organized rhythm in the absence of pulse with or without echocardiographic motion ("true PEA" vs. "pseudo-PEA"). In pseudo-PEA, pausing compressions and administering vasopressors may restore circulation.⁶⁸ Perfusion may be so poor that the pulse is absent in VT, supraventricular tachycardia, and atrial fibrillation, even with rapid ventricular response, and is also unresponsive to the filling of the heart. These tachydysrhythmias should be corrected by rescue shock.

The absence of perfusion with slow organized electrical activity may result from damage to the heart muscle (as in massive MI) or from uncoupling of electrical and mechanical activity (as in prolonged circulatory arrest). The rate of complexes may be used to monitor resuscitation efforts. With increasing ischemia, energy depletion will occur in the electrical system, and the rate of PEA will slow down. If resuscitation improves the energy state of the heart, the rate of PEA will accelerate. Narrow complexes reaching rates of 80 to 100 beats per minute often herald the return of a pulse. Falling rates reflect unsuccessful resuscitation efforts. The morphology of complexes in PEA may also point toward a simplified approach to this rhythm. Narrow complexes tend to indicate a mechanical issue, whereas wide complexes tend to indicate a metabolic derangement or agonal rhythm.⁶⁹

VF and asystole lie along a continuum of not-organized ECG. Arbitrary peak-to-peak amplitude of the ECG is usually used to distinguish asystole (amplitude <0.1-0.2 mV) from VF (amplitude >0.2 mV).⁷⁰ However, VF also exhibits temporal structures that may be absent in asystole.⁷¹ VF is a chaotic electrical activity formed by multiple interacting waves of activation within the heart.⁷² VF emerges from broken wavefronts that result from areas of ischemia (as in MI), areas of prolonged refractoriness (as in drug-induced or inherited prolonged QT intervals), or too-rapid succession of activation potentials (as in tachycardia or an "R on T" premature beat). As the organization and amplitude of these waves decline due to ischemia or hypoxemia, the amplitude of the ECG also declines. Reperfusion of the heart in asystole may restore VF. Furthermore, the amplitude and organization of the VF increases with reperfusion, providing a marker of adequate artificial perfusion.

Rational Use of Rescue Shocks for Defibrillation

Delivery of immediate transthoracic electric rescue shocks to patients in VF can convert VF into an organized cardiac rhythm. Rescue shocks are highly effective when VF is for a very brief duration (<1-2 minutes). These shocks may work by depolarizing the heart, canceling the

original wavefronts, or prolonging the refractory periods.⁷² Although rescue shocks can successfully restore an organized rhythm, repeated shocks may directly damage the myocardium.⁷³ Optimal therapy should provide rescue shocks at the lowest effective energy while minimizing the number of unsuccessful rescue shocks.

In the out-of-hospital setting when the collapse is not witnessed by paramedics, only 9% to 12% of rescue shocks restore an organized ECG,^{74,75} and most shocks convert VF into asystole.⁷⁶ Even after successful defibrillation, VF may recur because of incomplete depolarization by the shock, heterogeneous areas of refractoriness, or persistent foci of chaotic activity.⁷⁷ Multiphasic shock waveforms are more effective for depolarization of individual myocytes and require less energy than monophasic waveforms.⁷² Consequently, most available defibrillators deliver biphasic waveforms. Increasing pressure of paddles from 0.5 kg to 8 kg on the chest decreases transthoracic impedance by as much as 14% and increases delivery of current to the heart.^{78,79} This advantage of paddles must be weighed against the increased safety and convenience afforded by hands-free self-adhesive defibrillation pads, which are now used in most settings. In the past, multiple shocks would be delivered in rapid succession to decrease chest impedance. However, repetitive shocks decrease chest impedance by about 8% or less in actual patients,^{78,80,81} which does not justify the interruption of artificial circulation to deliver "stacked" shocks. Reducing the interruption in chest compressions before and after a rescue shock is associated with greater resuscitation success,⁸² which led to the coining of the term *perishock pause*. Duration of the perishock pause is inversely associated with survival to hospital discharge.⁸³ Specific techniques to reduce the perishock pause include continuing chest compressions while the defibrillator is charging, only stopping at the last moment prior to shock, and eliminating the postshock pulse check. Using gloves and modern self-adhesive defibrillation pads, the risk of shock to rescuers from touching a patient during defibrillation is small.²⁵ Manual compressions may be continued during rescue shocks, or even while using mechanical chest compression devices.

For VF that has lasted more than 3 to 4 minutes, preclinical data suggest that delaying rescue shocks until after a few minutes of chest compressions will improve success.⁸⁴⁻⁸⁷ To date, two clinical studies in out-of-hospital cardiac arrest patients have found that either 90 seconds or 3 minutes of chest compressions prior to delivery of the initial rescue shock improved resuscitation rates for subjects with VF outside a hospital, particularly when rescuer response intervals were longer than 4 minutes.^{2,88} However, a third study found no difference in outcome with 5 minutes of chest compressions prior to shock,⁸⁹ while a fourth study found no difference in outcome with 3 minutes of chest compressions prior to shock.⁹⁰ Finally, a large multicenter trial comparing immediate rescue shock to 3 minutes of chest compressions prior to rescue shock recently stopped enrollment, finding no difference between groups.⁹¹ Taken together, the clinical data suggest that the first rescue shock for VF should be delivered as soon as possible within 3 to 5 minutes as long as chest compressions are started immediately but that there is no reason to intentionally delay the rescue shock.

Quantitative analysis of the VF waveform can distinguish early VF from late VF and may be useful in estimating the likelihood of rescue shock success.⁹² Larger amplitude of VF⁹³ as well as frequency-based measures and nonlinear dynamic measures of VF organization⁹⁴⁻⁹⁷ are associated with a higher probability of rescue shock success. Future generations of defibrillators may provide real-time, semiquantitative estimates of the probability that a rescue shock will succeed in restoring an organized rhythm. It is unknown if these quantitative measures will be clinically useful for titrating resuscitation.

Beta-blockade with a short-acting agent such as esmolol represents another therapeutic option for VF. Beta-activation increases myocardial oxygen requirements, worsens ischemic injury, lowers the VF threshold, and worsens postresuscitation myocardial function.⁹⁸⁻¹⁰⁰ Blocking beta receptors may terminate the electrical storm responsible for refractory VF.⁹⁸⁻¹⁰² Esmolol is a favorable agent given its ultra-short half-life.¹⁰³

Drug Therapy

No drug therapy has been demonstrated to improve long-term survival.¹⁰⁴ Nonetheless, drug therapy in cardiac arrest can be divided into three categories: pressors, antidysrhythmics, and metabolic drugs. Pressors are used during resuscitation and include epinephrine and vasopressin. Both these drugs can increase CPP via the α -adrenergic (epinephrine) or vasopressin receptors (Fig. 50-6).^{105,106} Epinephrine is usually administered in 1-mg (~ 0.015 mg/kg) increments. In laboratory studies, the pressor effects of epinephrine during cardiac arrest were brief (~ 5 minutes). Vasopressin is administered as 40-unit boluses (~ 0.5 units/kg) and produces a longer lasting increase in CPP (~ 10 minutes). Both drugs should be titrated to improvement in clinical indicators (ECG waveform, mechanical activity, changes in end-tidal CO_2 or diastolic arterial pressure as a surrogate for CPP). Rote, repeated administration is unlikely to result in meaningful outcome improvements. This concept of goal-directed cardiac arrest resuscitation is an emerging paradigm within resuscitation science supported by preclinical¹⁰⁷ and preliminary clinical work.¹⁰⁸

Older clinical trials comparing higher initial boluses of epinephrine (15 mg vs. 1 mg) found a higher rate of pulse restoration (13% vs. 8%) and higher rate of admission to a hospital (18% vs. 10%),¹⁰⁹ but the overall survival was not significantly different. Comparison of moderate doses (7 mg vs. 1 mg) of epinephrine in both in-hospital and out-of-hospital cardiac arrest found no change in pulse restoration or survival.¹¹⁰ Likewise, comparison of 0.02 mg/kg versus 0.2 mg/kg epinephrine found no change in pulse restoration or survival.¹¹¹ It is possible that the β -adrenergic effect of these higher doses of epinephrine produces toxicity that limits long-term survival. Postarrest impairment of cardiac index and oxygen delivery has been related to epinephrine dose.¹¹² Likewise, neurologic impairment has also been related to epinephrine dose.¹¹³ Increasingly, it is recognized that higher doses of epinephrine may impair cerebral circulation, a detrimental effect that may offset any benefit from increasing rates of restoration of circulation.¹¹⁴ Titrated epinephrine infusions may balance these

positive and negative effects, but this approach has not yet been explored clinically.

Vasopressin can increase CPP without complicating β -adrenergic effects. Resuscitation rates and survival are identical for patients resuscitated with vasopressin and standard doses of epinephrine after in-hospital¹¹⁵ or out-of-hospital cardiac arrest.¹¹⁶ However, post hoc analyses suggest vasopressin may be superior for resuscitation and survival of patients whose first ECG rhythm is asystole and for those subjects requiring multiple doses of vasopressors.¹¹⁶ Subsequent studies examined the combination of epinephrine with vasopressin versus epinephrine alone for treatment of cardiac arrest.^{117,118} These studies found no difference in outcome with the different combinations of drugs. Therefore, use of either vasopressin or epinephrine is reasonable in the setting of a cardiac arrest, but vasopressin is not recommended instead of epinephrine in general practice.

Although preclinical and existing clinical data support the conclusion that vasoactive drugs during CPR can increase the probability of restoring spontaneous circulation, it is unclear whether these drugs actually improve overall survival. One trial in out-of-hospital cardiac arrest patients compared resuscitation without intravenous (IV) drugs to resuscitation with IV drugs.¹⁰⁴ In this study, IV drugs increased the rate at which the pulse was restored (32% vs. 21%) but not the rate of neurologic survival (9.8% vs. 8.1%). Likewise, a massive, population-based, matched cohort study found that prehospital epinephrine was associated with restoration of circulation but with lower probability of 1-month survival and favorable functional outcome.¹¹⁹ These data raise the worrisome possibilities that when IV drugs are required to restore cardiac activity, severe brain injury has already occurred, or that the drugs used have added to the brain injury.¹¹³

The role of antidysrhythmic drugs during cardiac arrest is equivocal.^{120,121} Atropine may relieve bradycardia when it is vagally mediated. However, nervous system influences on the heart are largely eliminated after more than 1 to 2 minutes of circulatory arrest. Therefore, there is little expectation that atropine will improve resuscitation from asystole or PEA. Lidocaine, procainamide, and bretylium have a

FIGURE 50-6 ■ Administration of a vasoactive drug, in this case vasopressin, can increase coronary perfusion pressure (CPP) produced by chest compressions. Note that CPP generated by chest compressions alone is below the 15 to 20 mm Hg believed necessary for restoration of circulation. However, aortic pressure (Ao) and thus CPP increase above this threshold 40 to 60 seconds after drug administration (arrow), while right atrial (RA) pressure remains unchanged. When treating cardiac arrest, it is reasonable to expect the vasoactive drug will act after 60 more seconds of chest compressions. (Unpublished laboratory data.)

long history of use in the treatment of VF. Once VF is established, lidocaine can increase the electrical energy required to defibrillate by more than 50%.¹²² Other classes of antidysrhythmics without sodium channel blockade do not alter defibrillation energy requirements. For example, amiodarone (5 mg/kg) is superior to placebo¹²³ and to lidocaine¹²⁴ in terms of restoring the pulse in out-of-hospital patients with VF that is not terminated by three rescue shocks. A large clinical trial comparing amiodarone, lidocaine, or placebo for shock-refractory VF found no overall difference in survival.¹²⁵ However, both lidocaine and amiodarone were superior to placebo in the subgroup of witnessed VF.

Empiric treatments of metabolic disturbances with bicarbonate or other buffers may improve acidemia resulting from ischemia. While systems with increased use of bicarbonate report higher rates of successful resuscitation,¹²⁶ no trial has demonstrated that sodium bicarbonate administration improves outcome.¹²⁷ Aminophylline has been proposed as an antagonist of adenosine released during ischemia. Two prospective studies of aminophylline administration to subjects with PEA or asystole found no improvement in resuscitation.^{128,129} Use of dextrose-containing fluids versus dextrose-free fluids did not alter outcome for out-of-hospital cardiac arrest patients.¹³⁰ Other metabolic therapies including calcium and magnesium also lack supporting data.^{131,132} However, it is appropriate to consider specific use of these agents to correct known abnormalities that are contributing to cardiac arrest, such as known hyperkalemia, calcium channel blocker overdose, torsades, or hypomagnesemia.

Taken together, the data support a simple pharmacologic approach to the treatment of cardiac arrest: vasopressors, epinephrine, or vasopressin can augment CPP generated during chest compressions, antidysrhythmic drugs may be useful for maintaining organized rhythms in witnessed shock-refractory VF, and all other drug therapies should be based on the clinical situation and the response of the patient.

ASPECTS OF CARDIAC ARREST IN SPECIFIC SITUATIONS

If the original etiology of cardiac arrest is available, treatment and prognosis can be individualized to the specific patient. Among out-of-hospital patients, as many as 66% have primary cardiac disturbances.¹³³ For in-hospital patients experiencing cardiac arrest, dysrhythmia and cardiac ischemia account for 59% of events.¹⁴ This section reviews unique features of cardiac arrest resulting from both cardiac and noncardiac causes.

Primary Cardiac Events

Primary dysrhythmia or cardiogenic shock is the most common proximate cause of cardiac arrest.^{133,134} Patients undergoing angioplasty have a 1.3% incidence of cardiac arrest, and survival in these patients resembles survival in other populations.¹³⁵ Among patients admitted to a hospital with acute MI, cardiac arrest occurs in 4.8%.¹⁷ Dysrhythmias are common during the hours after reperfusion therapy,¹³⁵ although reperfusion therapy reduces the overall risk of cardiac arrest.¹³⁶ During acute MI, cardiac arrest is most likely to occur in patients with lower serum potassium levels, more than 20 mm of total ST elevation, and a prolonged QTc interval during the first 2 hours of their event.¹³⁶ Some 3.3% of subjects surviving acute MI suffered sudden cardiac death.¹³⁷ Abnormalities of the heart are present in most cases of cardiac arrest, with coronary artery disease present in at least 65% of autopsies.¹³⁸ Taken together, these data suggest that most patients with cardiac arrest will have contributing cardiovascular disease.

When angiography was performed on consecutive patients resuscitated from cardiac arrest, acute coronary artery occlusion was identified in 48% to 58% of the patients.^{139,140} Similarly, 51% of initially resuscitated outpatients exhibited an elevation in cardiac enzymes or

ECG evidence of acute MI.¹⁴¹ In one series, troponin T was elevated in 40% of out-of-hospital patients undergoing CPR.¹⁴² The direct myocardial injury from defibrillation and CPR may cause spurious elevations of creatine kinase that are unrelated to cardiovascular disease.¹⁴³ However, elevation in cardiac troponin levels are believed to reflect acute MI rather than injury from electric shocks.¹⁴⁴ Thus, the 40% of subjects undergoing CPR with elevated troponin probably suffered myocardial injury prior to collapse.

Unless a clearly noncardiac etiology for cardiac arrest is evident, acute coronary angiography may reveal an indication for angioplasty, thrombolysis, or other reperfusion therapy. Early reperfusion therapy is associated with improved survival and outcome.^{17,139,145,146} Primary revascularization is safe in comatose patients undergoing hypothermia treatment, and good outcomes have been reported.^{147,148} Therefore, coma and its treatment should not delay emergent treatment of acute coronary syndrome if suspected.

Primary ventricular tachydysrhythmias are rapidly reversible and are the initially recorded rhythm in 23% to 41% of out-of-hospital cardiac arrest patients^{10,11,149} and in 25% of in-hospital cardiac arrest patients.¹⁴ Long-term antidysrhythmia treatment should be considered for patients who survive sudden cardiac arrest. At a minimum, treatment should be considered for patients with decreased left ventricular function or primary dysrhythmia without a reversible cause.¹⁵⁰ Importantly, subjects surviving a life-threatening ventricular dysrhythmia have a 15% to 20% risk of death during a mean of 16 months of follow-up, even when a reversible cause of the dysrhythmia such as electrolyte disturbance or hypoxia is identified.¹⁵¹ Implantable defibrillators are superior to antidysrhythmic drugs for reducing the risk of subsequent death.¹⁵² This benefit is primarily in subjects with a left ventricular ejection fraction (LVEF) less than 0.35.¹⁵³ Implantable defibrillators were not better than antidysrhythmic drugs in a European trial that enrolled subjects resuscitated from cardiac arrest secondary to ventricular dysrhythmia without regard to LVEF.¹⁵⁴ Nevertheless, these devices offer significant hope of preventing sudden cardiac death, and identification of patients that they may benefit is an active area of research. At present, implantable defibrillators should be discussed for patients who recover from coma with LVEF less than 0.35 or who survive a ventricular arrhythmia in the absence of clearly reversible causes.

Asphyxia

Asphyxia causes transient tachycardia and hypertension, followed by bradycardia and hypotension, progressing to PEA or asystole. This period of blood flow with severe hypoxemia prior to cardiac arrest may make asphyxiation a more severe injury than VF or other rapid causes of circulatory arrest.¹⁵⁵ Brain edema is more common on CT scans after resuscitation when cardiac arrest is caused by pulmonary rather than cardiac etiologies.¹⁵⁶ During cardiac arrest, pulmonary edema develops from redistribution of blood into the pulmonary vasculature,¹⁵⁷ worsening oxygenation in the asphyxiated patient. Attention to the primary cause of asphyxia, as well as to maneuvers that will increase oxygenation, may be necessary.

Pulmonary Embolism

Pulmonary emboli may occur in postsurgical patients, as well as in medical patients with impaired mobility.¹⁵⁸ In two series, pulmonary emboli were present in 10% of both in-hospital deaths¹⁵⁹ and out-of-hospital deaths.¹⁶⁰ Pulmonary emboli can result in rapid cardiopulmonary collapse and should be considered as a possible etiology of cardiac arrest in the proper clinical setting or when collapse is preceded by sudden shortness of breath, hypoxemia, and/or pleuritic chest pain.

Pulmonary emboli cause cardiac arrest from hypoxemia or when a large thrombus obstructs right ventricular outflow into the pulmonary arteries. This situation results in a dilated, distended right ventricle and an empty left ventricle, which can be seen on a transthoracic

echocardiogram. Circulation cannot be restored unless this obstruction is relieved. Because the primary disturbance is hypoxemia and decreased cardiac output, cardiac arrest from pulmonary embolism often presents with an initial rhythm of PEA or asystole.

Administration of a bolus of fibrinolytic drugs such as tenecteplase has been used with reported success in nonrandomized trials during resuscitation of undifferentiated patients,¹⁶¹ but it failed to demonstrate benefit in a larger randomized trial of undifferentiated patients in cardiac arrest.¹⁶² Likewise, a randomized trial of tissue plasminogen activator to patients for out-of-hospital cardiac arrest with an initial rhythm of PEA failed to demonstrate any benefit.¹⁶³ There are few data on the treatment of cardiac arrest resulting from massive pulmonary emboli, and individual decisions to use fibrinolytics in this setting must be tempered by the low probability of success.

Electrolyte Disturbances

Potassium disturbance is the most likely electrolyte disturbance to result in cardiac arrest. In cardiac patients, hypokalemia has been linked to the incidence of VF after MI.^{136,164} Hypokalemia may also account for the increased incidence of sudden death in patients taking large doses of diuretics. VF is rare in patients where serum potassium is maintained over 4.5 mEq/L. Conversely, hyperkalemia can prolong repolarization, increasing the likelihood of VF initiation. Hyperkalemia may also suppress automaticity in the myocardial electrical system, leading to bradycardic PEA or asystole. Interestingly, cardiac arrest occurring during hemodialysis is not associated with high or low potassium levels but is more common after patients are dialyzed against a low (0 or 1 mEq/L) potassium dialysate.¹⁶⁵ These data suggest that rapid changes in potassium rather than the absolute value are important triggers of cardiac arrest in this population. Derangements of calcium and magnesium may produce similar or synergistic changes in cardiac conduction.

The clinical setting of cardiac arrest or widened ventricular complexes with repolarization abnormalities on ECG may suggest a primary electrolyte disturbance. If hyperkalemia is suspected, the usual acute resuscitation maneuvers can be supplemented by a bolus injection of calcium carbonate (1 g), bicarbonate (1 mEq/kg), and perhaps insulin (0.1 units/kg) with glucose (0.5 to 1 gm/kg). These drugs may improve cardiac electrical stability, facilitating restoration of circulation.

Poisoning

Cardiac arrest can result from drug overdose. Therapy does not change except when specific antidotes or countermeasures to the poison are available. For example, calcium channel blocker overdose may be countered by administration of IV calcium.¹⁶⁶ Beta-blocker toxicity may require large doses of inotropic agents¹⁶⁷ or may respond to glucagon.¹⁶⁸ Digoxin overdose may respond to digoxin-binding antibodies.¹⁶⁹ In the case of narcotic-induced respiratory depression, subsequent cardiac arrest is usually a specific case of asphyxia rather than specific cardiotoxic effects. Case reports have suggested treating local anesthetic toxicity with 1 to 3 mL/kg of Intralipid.¹⁷⁰ This intervention is likely to be explored for other lipid-soluble poisonings.¹⁷¹ Poisoned patients are often younger with few comorbidities and may recover well once the poison is eliminated. This potential for a better outcome may justify longer and more aggressive efforts at resuscitation. A recent cohort study of recreational drug overdose-related cardiac arrest found that overdose-related patients who survived to hospital discharge were more likely than other cardiac arrest patients to have a favorable discharge disposition.¹⁷²

Sepsis

Cardiac arrest developing from sepsis may involve direct myocardial depression from humoral factors.^{173,174} Vasodilation also results in apparent hypovolemia. Finally, impaired oxygen extraction, shunting,

and mitochondrial depression can produce cellular hypoxia. Because pump and vascular failure are the principal physiologic derangements, the most common initial ECG rhythm would be expected to be a rapid PEA that slows to asystole with ischemia. Large doses of inotropes, vasoconstrictors, and volume may be needed to restore circulation. Acute volume resuscitation may require 100 mL/kg of isotonic fluids or more and must be titrated to physiologic endpoints (for example, central venous oxygen saturation, CVP, or urine output). Because the underlying sepsis physiology will still be present when the pulse is restored, these patients may prove exceedingly unstable during the subacute recovery period and have a reduced chance of survival.^{30,175-177}

Trauma/Hemorrhage

Hypovolemic cardiac arrest occurs after severe trauma, gastrointestinal hemorrhage, or other blood loss. Absence of venous return results in an empty heart that cannot produce cardiac output despite a normal inotropic state and vascular tone. As with sepsis, this situation would most likely present with a rapid PEA that slows to asystole, but VF can develop in response to global ischemia. Because cardiac function and vascular function are initially normal, inotropes and vasoconstrictors are unlikely to benefit hypovolemic cardiac arrest. Likewise, during hypovolemic cardiac arrest, the empty cardiac ventricles render external chest compressions ineffective. As such, there is no physiologic justification to employ the same resuscitation measures that are used for more traditional cases of cardiac arrest. Instead, attention should be turned toward emergent procedures to control hemorrhage, intravascular volume expansion with crystalloid fluids or blood products,¹⁷⁸ and mobilization toward definite surgical repair. After restoration of circulation, patients with hemorrhagic cardiac arrest are likely to develop multisystem organ failure.¹⁷⁸

If blood loss is ongoing or if massive volume replacement cannot be rapidly instituted, thoracotomy allows clamping or compression of the aorta, perhaps retaining sufficient blood in the proximal aorta to perfuse the coronary and cerebral arteries. This procedure has reported success in the treatment of penetrating traumatic injuries¹⁷⁹ but not in blunt trauma.¹⁸⁰ Survival is better if thoracotomy occurs in the operating room after a brief loss of pulse and best if the penetrating injury has created a cardiac tamponade that is directly relieved by pericardiectomy. Clearly, restoration of circulation must be accompanied by repair of the site of hemorrhage.

Hypothermia

Hypothermia represents an important situation where prolonged resuscitative efforts are justified by the greater tolerance of the cold heart and brain to ischemia. Survival with favorable neurologic recovery has been reported after cold water submersion or exposure, with cardiac arrest, and resuscitation efforts lasting several hours.^{181,182} Subjects in whom circulatory arrest occurs because of hypothermia appear to be more salvageable than subjects who asphyxiate or have circulatory arrest prior to becoming cold.¹⁸³

Treatment should be based upon the initial temperature of the patient. For temperatures between 32°C and 37°C, no change in drug or electrical treatment is required, and this level of hypothermia may be beneficial for resuscitation of both brain and heart.^{184,185} For temperatures between 29°C and 32°C, cardiac activity may be preserved, and external warming (warm air, heating lights, warm blankets) and warm IV fluids should accompany usual resuscitation efforts. The likelihood of generating sufficient perfusion to rewarm the body declines as temperatures decrease from 32°C to 29°C, and more invasive warming should be considered if external warming fails to elicit a rapid response. Mechanical and electrical activity of the heart is disrupted at temperatures below 28°C, and patients may exhibit PEA, VF that is refractory to defibrillation attempts, or asystole. Repetitive rescue shocks in such patients are not justified and may be detrimental; instead, rescue shocks should

be reserved until the patient has been rewarmed in the setting of ongoing circulatory support. Efficacy of most resuscitation drugs may be impaired.

Active rewarming during resuscitation of victims of severe hypothermia can include arterial and venous access for partial or complete cardiopulmonary bypass. Extracorporeal circulation is particularly useful because it can provide artificial circulation and warming, simultaneously.^{183,186,187} Another option is the placement of thoracostomy tubes and lavage of the chest with warm fluids.¹⁸⁸ Thoracostomy is intuitively preferable to peritoneal lavage because the heart is directly warmed. Warm air forced over the body surface provides the least heat exchange.¹⁸⁹ In any case, it is difficult to determine whether or not circulation can be reestablished in profoundly hypothermic patients until near physiologic core temperatures (32°C to 36°C) are restored.

Other Medical Conditions

Comorbidities have a tremendous influence on the outcome of patients with cardiac arrest.^{134,190,191} In some cases, cardiac arrest may be an expected progression of the patient's disease. For example, no survivors were reported among cancer patients with expected cardiac arrest.¹⁹¹ Therefore, it may be appropriate to set limits on resuscitation efforts in certain medical conditions prior to cardiopulmonary collapse. Ideally, discussion about the expectations for resuscitative efforts should be held with the patient, his or her family, or the patient's representatives prior to cardiac arrest. If those discussions did not occur prior to the first cardiac arrest, they should promptly follow any initially successful resuscitation.

POSTCARDIAC ARREST CARE TO MINIMIZE BRAIN INJURY

Postcardiac arrest syndrome is a defined clinical entity, consisting of brain injury, myocardial dysfunction, systemic ischemia/reperfusion, and the persistent precipitating pathology that caused the cardiac arrest. Management of this syndrome in patients after restoration of circulation directly affects their ultimate outcome. For example, survival varies for comparable patients treated by a single ambulance service who are delivered to different hospitals with institutional differences in in-hospital management.^{5,6} The American Heart Association and European Resuscitation Council now incorporate guidelines for the treatment of post-cardiac arrest syndrome into their consensus scientific statement. This section will highlight a bundled post-cardiac arrest care package, designed to mitigate primary injury and prevent secondary brain injury.

Brain injury after ischemia is an active process that develops over hours to days after resuscitation. Multiple cellular and molecular mechanisms contribute to this brain injury.¹⁹² Mechanisms include increased release of excitatory amino acids, free radicals, and energy failure. Protein synthesis is inhibited at the level of translation initiation for several hours.¹⁹³ There are focal disturbances of cerebral blood flow.¹⁹⁴ Specific intracellular and extracellular signaling pathways are activated for several hours after brain ischemia,^{195,196} which may lead to specific changes in gene transcription. Finally, activation of specific proteases between 24 and 72 hours after reperfusion is associated with the appearance of histologic signs of neuronal death.¹⁹⁷ The relative contribution of each of these processes to neuronal injury and their potential as targets for therapeutic intervention are unknown.

Despite detailed knowledge of the mechanisms involved with brain ischemia, no drug to date has demonstrated a clear benefit in human trials. Randomized trials have examined thiopental, the calcium channel blocker lidoflazine, magnesium, and diazepam.¹⁹⁸⁻²⁰⁰ One explanation for this failure is that multiple mechanisms contribute simultaneously to the process of ischemic neuronal death. Antagonizing one pathway leading to neuronal death may leave

other backup mechanisms unaffected. Less specific therapies may prove more effective. For example, two prospective randomized clinical trials found that induction of whole-body mild hypothermia (32°C to 34°C) for 12 to 24 hours after resuscitation improved survival and neurologic recovery.^{184,201} Whether this type of temperature management itself conferred an actual benefit or just served to prevent deleterious hyperthermia, it is important to note the success of this type of systemic therapy. Observational data also support coronary revascularization and meticulous avoidance of hyperthermia, hypotension, hypocarbia, hypoxia, and hyperglycemia.^{5,202-204} Taken together, systematic brain-oriented intensive care, rather than a single therapeutic drug or intervention, is required to improve outcome (Table 50-2).

Coronary Revascularization

Given the prevalence of acute coronary occlusions and high-risk coronary artery disease in this population, appropriate treatment of acute coronary syndrome or ST elevation MI (STEMI) should be promptly

TABLE 50-2 Postcardiac Arrest Intensive Care

| | |
|----------------------------|---|
| TEMPERATURE | Targeted temperature management 33°C to 36°C for 24 hours or longer Rewarm slowly (<0.25°C/h) Avoid fever for 48 hours or until awake |
| CARDIOVASCULAR | Mean arterial pressure >80 mm Hg during first day (inotropic and vasopressor support as needed; invasive monitoring as needed) Reperfusion therapy for acute myocardial infarction, regardless of concurrent coma or treatment with hypothermia Medical management for acute coronary syndromes (antiplatelet drugs, anticoagulation) |
| PULMONARY | Avoid hyperventilation Avoid hypoxia or unnecessary hyperoxia Pneumonitis is common |
| GASTROINTESTINAL | Usual care Consider early refeeding (after hypothermia) to reduce translocation |
| FLUIDS/ELECTROLYTES | Monitor CVP and urine output with hypothermia/rewarming Monitor potassium/electrolytes during temperature changes Keep potassium ≥4.5 mEq/L Monitor glucose frequently, normal treatment of hyperglycemia >180 mg/dL |
| INFECTION | Pneumonia is common Prophylactic antibiotics are of unproven benefit Antipyretics are reasonable |
| NEUROLOGIC | CT scan to exclude intracranial lesions Sedation and muscle relaxation as needed for targeted temperature management Monitor for seizures with continuous EEG Suppress malignant EEG patterns with antiepileptic therapy Serial clinical examinations for prognosis Examinations may change dramatically over first 72 hours (or longer with hypothermia treatment) EEG, SSEP, and MRI with DWI can supplement clinical examination for prognosis in selected patients Consider pharmacologic stimulation in patients with intact SSEP but persistent coma |

CT, computed tomography; CVP, central venous pressure; DWI, diffusion-weighted imaging; EEG, electroencephalogram; MRI, magnetic resonance imaging; SSEP, somatosensory evoked potential.

initiated, regardless of initial level of consciousness.²⁰⁵ Furthermore, emergent coronary angiography is reasonable even in the absence of STEMI because acute coronary ischemia is such a common precipitant of cardiac arrest. Repeated observational studies have highlighted immediate coronary angiography with concomitant coronary intervention as an independent predictor of survival and favorable neurologic outcome, irrespective of the presence or absence of STEMI on the initial ECG.^{139,140,146,206,207} There has been no randomized trial of this therapy to date.

Targeted Temperature Management

Meticulous temperature control is important during the first 24 to 48 hours after ischemic brain injury. Bacteremia and spontaneous fever are common in resuscitated patients, making active prevention of hyperthermia mandatory.^{208,209} Fever prevention is beneficial to the injured brain after traumatic brain injury, stroke, and cardiac arrest.^{202,210,211} Mechanistically, temperature probably affects more than the brain metabolic rate (manipulations of temperature that improve neurologic recovery in laboratory studies produce no effect on jugular venous lactate or oxygen uptake).²¹² Instead, a variety of signaling pathways and cellular responses are sensitive to relatively small (1°C to 2°C) changes in brain temperature.^{195,196} Also, lowering brain temperature can reduce intracranial pressure,²¹³ as well as vulnerability to seizures.²¹⁴

For more than a decade, mild induced hypothermia (32°C to 34°C) for 12 or 24 hours has been the cornerstone of post-cardiac arrest intensive care. Two randomized trials published in 2002 found a 24% to 30% reduction in relative risk for death or poor neurologic outcome²¹⁵ and significant improvement in the odds of survival and good neurologic outcome for subjects resuscitated from VF cardiac arrests.^{184,201} More recently, a large, prospective, randomized trial comparing a targeted temperature of 33°C with 36°C found that both groups had similar mortality and neurologic outcome at 180 days.²¹⁶ The most notable difference between the 2002 trials compared with the more recent trial was that the earlier studies did not adequately control temperature in the control arm. Temperatures greater than 37°C occurred in subjects for both control groups, whereas tight control at 36°C was followed in the more recent trial. Additionally, the recent trial used a blinded neurologic assessment along with regimented decisions about prognosis. While controlling temperature at 36°C is not superior to a strict temperature control at 33°C, it is not clear what temperature is best for patients who differ from the study population. Patients in the 33°C versus 36°C trial had very high rates of witnessed cardiac arrest, bystander CPR, initial shockable rhythm, and very brief intervals from collapse until start of basic life support. It is possible that unidentified subgroups of patients may benefit from a specific target temperature or from titrated use of temperature.

Current recommendations are to keep all comatose post-cardiac arrest patients at a constant target temperature ranging between 32°C and 26°C. This is different from reactive treatment of fever, which has not been studied in clinical trials. It is erroneous to assume that selection of 36°C as a target temperature is synonymous with not managing temperature or fever prevention without active controls. Active measures require thermostatically controlled devices, of which there are many. Importantly, there is no clinical situation where control of temperature in this range is contraindicated; even bleeding does not increase at 36°C.

There is no biological basis to believe that the neurologic benefit of temperature management is specific to patients with one type of cardiac rhythm. Patients with all rhythms were included in the largest clinical trial.²¹⁶ Multiple case series report successful application of induced hypothermia for patients after out-of-hospital and in-hospital cardiac arrest with all initial rhythms.^{3,217,218} At the time of resuscitation, many patients were already mildly hypothermic, with core temperatures between 35°C and 35.5°C.^{184,201,219} This spontaneous cooling may result from the mixing of core and peripheral blood

compartments during circulatory arrest, but patients typically rewarm within a few hours unless specific interventions are instituted.^{202,220}

The optimal duration of temperature management, the maximum delay in achieving target temperatures, the optimal target temperature, and the preferred rate of rewarming are unknown. Laboratory studies suggest that cooling to a range from 32°C and 35°C for 12 to 24 hours is beneficial, particularly if cooling is achieved within 6 hours after resuscitation. These studies also suggest that rewarming should be performed slowly (<0.25°C/hour). A regimen similar to the largest clinical trial (24 to 28 hours, followed by meticulous fever suppression for at least 3 days) is reasonable.²¹⁶

After cardiac arrest, temperature management can be achieved by a variety of techniques including surface cooling with ice packs, cooling blankets or endovascular devices.^{185,201,221} Initial studies using surface cooling alone suggested that it is slow and may require 4 to 6 hours to reach 34°C.^{184,210,222} However, neuromuscular blockade and sedation to prevent shivering greatly accelerate surface cooling.²²³ There are few direct comparisons of surface cooling and endovascular cooling; however, endovascular catheters may provide more stable control of temperature over time.^{224,225} Local cooling of the head is unlikely to produce brain hypothermia when there is adequate perfusion by warm core blood,²¹⁹ although the head can be an effective site for removing heat from the body.²²⁶

Rapid infusion of 30 mL/kg cold (4°C) crystalloid fluid produces a rapid decrease in core temperature in post-cardiac arrest patients.^{220,227-229} Cold fluid boluses must be administered quickly into the central circulation (via a central line or under pressure infusion via a peripheral line). The volume required may limit this intervention in some patients. Recent clinical trials show no beneficial outcome when paramedics use cold intravenous fluids for undifferentiated cardiac arrest patients prior to hospital arrival and instead observe an increase in complications.²³⁰⁻²³² Therefore, this intervention is best used in a hospital critical care setting with adequate monitoring and resources. Cold IV fluids only produce a transient decrease in core temperature, requiring that a maintenance technique (endovascular or surface cooling device) be in place after the infusion.^{220,229}

Induction of cooling can result in peripheral vasoconstriction, with an apparent reduction in vascular volume, rise in CVP, and diuresis.²³³ Rewarming causes vessels to dilate, CVP to fall, and the patient to appear relatively hypovolemic. Inattention to these fluid shifts was cited as a pitfall in trials of therapeutic hypothermia for traumatic brain injury.²³³ Hypokalemia, hypophosphatemia, and hypomagnesemia also occur during cooling, followed by hyperkalemia during rewarming.^{234,235} Frequent monitoring and correction of electrolytes are warranted.

Primary angioplasty is safe in patients undergoing hypothermia treatment.^{147,148,185} Mild hypothermia greater than 30°C does not interfere with defibrillation. Cooling from 37°C to 31°C has a positive inotropic effect, increasing stroke volume to a greater extent than it decreases heart rate.²³⁶ Clinical data report a transient 18% decline in cardiac index with cooling to 33°C.²³⁷

Infections may become more common when patients are cooled for 24 hours or longer.^{184,201} Although mild hypothermia can inhibit platelet function and coagulation,²³⁸ these changes are of a smaller magnitude, leading to few bleeding complications, even in subjects with concurrent trauma or administration of heparinoids and glycoprotein IIb/IIIa inhibitors.^{185,210} Bleeding after hypothermia and cardiac catheterization was reported in 6.2% of post-cardiac arrest patients.²³⁹ Elevation in pancreatic enzymes has been reported in cooled patients, but these changes resolve with rewarming.^{184,237} Creatinine clearance and platelet count may fall during cooling, but both parameters normalize with rewarming.²³⁷

Hemodynamic Management

Myocardial function declines transiently after cardiac arrest.²⁴⁰ Oxidative stress or other triggers can lead to myocyte damage after reperfusion.²⁴¹ Clinically, some vasoactive and/or inotropic drug support is

necessary in a large proportion of patients resuscitated from cardiac arrest, with expected recovery over the subsequent 24 to 48 hours.

During the first day after resuscitation from cardiac arrest, patients exhibit increased cerebral vascular resistance²⁴² and impaired cerebral autoregulation.^{243,244} When autoregulation is present, it is right-shifted such that brain perfusion declines when mean arterial pressure (MAP) declines below 80 to 120 mm Hg. When blood pressure is maintained, clinical positron emission tomography (PET) studies suggest that regional perfusion remains matched to metabolic activity after cardiac arrest.^{245,246} Thus, available data indicate that perfusion of the brain requires a higher MAP than normal during the first hours to days after cardiac arrest. Periods of hypotension after the pulse is restored may add significant secondary ischemic brain injury.

If tolerated by the heart, relative hypertension (MAP of 80 to 100 mm Hg) should be considered using inotropes and/or pressors to prevent brain hypoperfusion. Episodes of hypotension after resuscitation are associated with death and poor neurologic recovery in postarrest patients.^{203,247} Conversely, higher MAP is associated with survival and better neurologic recovery.^{248,249} Hemodynamic management strategies are not well defined in most postarrest care implementation studies,²⁵⁰ and no specific choice of pressors has been demonstrated to be superior. Dopamine (5–20 µg/kg/min), norepinephrine (0.01–1 µg/kg/min), and/or epinephrine (0.01–1 µg/min) are all potential agents. Dopamine has the disadvantage of inducing tachydysrhythmias. Conversely, epinephrine has more positive inotropy than norepinephrine but can prolong lactic acidosis. Therefore, the choice and doses of these agents must be titrated to individual patients.

Oxygenation and Ventilation

Postcardiac arrest hyperoxia ($\text{PaO}_2 \geq 300$ mm Hg) was associated with higher inpatient mortality than normoxia.^{251,252} These studies speculate that high oxygen concentration increases oxidative free radical damage. One multicenter cohort study found a linear, dose-dependent relationship between levels of oxygen tension and inpatient mortality but could not identify a single threshold for harm.²⁵³ In the absence of evidence to support a specific PaO_2 goal for patients, it is reasonable to titrate FiO_2 to the lowest values sufficient to maintain a normal arterial oxygen-hemoglobin saturation (94% to 98%).

Although the post-cardiac arrest brain suffers from impaired cerebral autoregulation, it tends to preserve CO_2 reactivity.²⁴⁴ Both hypocapnia ($\text{PaCO}_2 \leq 30$ mm Hg) and hypercapnia ($\text{PaCO}_2 \geq 50$ mm Hg) are independently associated with poor neurologic outcome.²⁵⁴ As in traumatic brain injury, hypo- and hyperventilation result in dysfunctional cerebral perfusion, so it is best to ventilate with a goal of normocarbia (PaCO_2 35 to 45 mm Hg).

Glucose Control

Elevated serum glucose is common after cardiac arrest and is associated with poor outcome,^{130,255} but hyperglycemia may simply be a marker of greater illness severity. Both epinephrine and physiologic stress can elevate serum glucose, and mild hypothermia may reduce insulin sensitivity.²⁵⁶ However, multivariate models that account for resuscitation time and medication usage show an effect of serum glucose on admission and the first 48 hours of intensive care on long-term outcome.^{5,257} Monitoring of glucose and treatment of hyperglycemia are reasonable.

Intensive glycemic control with a low target range (72–108 mg/dL, 4–6 mmol/L) has not proven beneficial outside of the surgical population where it was first studied¹²⁵⁸ and may be harmful in medical intensive care.^{259,260} After cardiac arrest, there was no difference in outcome when a moderate glucose range was targeted (108–144 mg/dL; 6–8 mmol/L) versus a strict lower range (72–108 mg/dL; 4–6 mmol/L).²⁶¹ However, the incidence of hypoglycemic events was higher in the strict versus moderate control group (18% vs. 2% of patients). Given the available data, treatment of glucose levels above 180 mg/dL (10 mmol/L) is reasonable.

Hematologic Changes

Cardiac arrest is associated with activation of coagulation that is not balanced by fibrinolysis and is perhaps related to ischemic injury to the endothelium. This hematologic profile is reminiscent of disseminated intravascular coagulation and may contribute to subsequent end organ dysfunction. Markers of thrombogenesis that have been reported include increased thrombin-antithrombin complexes and fibrinopeptide A.^{262,263} These increases are not balanced by fibrinolytic factors for at least 24 hours.

At present, use of anticoagulation is variable, and there are no prospective trials evaluating the effect of empiric anticoagulation after resuscitation. Anticoagulation and even fibrinolytic drugs are safe after CPR.^{162,263–265} A retrospective series noted a univariate relationship between anticoagulation and 6-month survival that was not significant in a multivariate model.²⁵⁷ Given the hematologic evidence of active thrombogenesis, anticoagulation should be considered whenever there is a possibility of a thrombotic etiology.

Infection

Both ischemia-triggered systemic inflammatory responses and infections are common after cardiac arrest.²⁶⁶ Pneumonia, bloodstream infections, and catheter-related infections are the most common infectious complications.^{266,267} Pneumonia, especially, is associated with the duration of mechanical ventilation and length of ICU stay but does not appear to have an impact on mortality or neurologic outcome.^{266–268} Bacteremia occurs in 39% of patients during the first 12 hours after resuscitation.²⁰⁸ The accurate diagnosis of post-cardiac arrest infections is hampered by an associated increase in inflammatory markers^{269,270} and body temperature control. Despite these observations, the role of prophylactic antibiotics or antipyretics is unknown, and selective treatment of identified infections is reasonable.

PREDICTING NEUROLOGIC RECOVERY

The goal of clinical practice is always to restore the patient to full consciousness and function.²⁷¹ All patients with circulatory arrest of more than 1 or 2 minutes will be comatose at initial presentation, but some of these patients can recover and awaken. Therefore, signs of neurologic activity immediately after restoration of circulation are encouraging, but their absence does not preclude eventual recovery. Unfortunately, many cardiac arrest survivors fail to completely awaken and may meet criteria for a persistent vegetative state.^{272,273} The status of patients who do not quite meet these criteria but are not awake has been described as a minimally conscious state.²⁷⁴ Less than 10% of patients who are hospitalized after cardiac arrest progress to formal brain death.²³

Determining the neurologic prognosis of patients resuscitated from cardiac arrest has been the subject of multiple reviews and guideline statements^{275–278} before and after the setting of modern ICU care. It remains unclear whether the traditional findings associated with poor outcome^{279–281} are still valid in the setting of modern ICU care and targeted temperature management. In fact, good survival has been reported after some situations previously believed to have universally poor outcomes such as post-cardiac arrest status myoclonus and seizures^{282,283} or the absence of cortical responses on evoked potentials.²⁸⁴ Neurologic recovery continues over a longer time period than the 3 days recommended in historical publications.^{275,276} Therefore, longer periods of support and observation are appropriate for many patients. Furthermore, a multimodal approach to determining prognosis that includes imaging and neurophysiologic studies may be useful to sort out difficult cases in which the physical examination is equivocal.²⁸² In a practical approach, the clinician can make an initial estimate of the probability of recovery based on clinical exam. As more information becomes available from clinical progression, imaging studies, and neurophysiologic studies, this estimate can be revised in order to advise families and proxy decision makers. Daily reevaluations are

required to decide if ongoing therapy is consistent with the patient's goals in light of the best estimate of the probability of various outcomes.

Baseline Probability of Recovery

In cohorts of patients admitted to a hospital after in-hospital and out-of-hospital cardiac arrest, approximately 31% to 33% of patients recovered to a favorable functional status.^{22,23} While clinicians could start with an estimate that all patients have about 30% chance of good recovery, it is obvious that some patients have much greater illness severity than others at admission. The expectation of survival should be revised based on this fact. Various prognostic tools or scores can refine the estimated odds of recovery based on initial physiologic status or historical features.^{285,286} One simple score is the Pittsburgh Cardiac Arrest Category (PCAC) (Box 50-1). This score divides patients into four categories based on initial coma examination and degree of cardiopulmonary failure.²⁸⁷ Probability of survival, good functional recovery, and risk of multiple organ failure varies by category. This score has advantages of being fast, easy to communicate, and validated in prospective cohorts.²⁸⁸ Using some initial assessment of illness severity is a reasonable practice for the clinician who wants to provide realistic estimates for families or surrogate decision makers.

Clinical Examination

A classic case series found that pupillary reflexes, corneal reflexes, and motor activity can change over the first 72 hours after resuscitation.²⁸¹ By 72 hours, persistent absence of pupillary light reflex and corneal response is highly predictive of permanent coma,^{277,278} but the motor examination is much less reliable. Specifically, motor response less than flexion at 3 days was reported to have a false-positive rate ([FPR] percentage where tests predict a poor outcome, but patients have a good outcome) of 14% (95% confidence interval [CI], 3%-44%)²⁸⁹ or 8% (95% CI, 2%-25%).²⁸² In contrast, among patients not treated with therapeutic hypothermia, the absence of pupillary light reflex (>72 hours) after cardiac arrest has an FPR 0% (95% CI, 0%-8%) for

predicting death or vegetative state. The presence of myoclonus is not reliable for predicting poor outcome and must be distinguished from status myoclonus (persistent, repetitive myoclonus). Status myoclonus on admission is associated with death or vegetative state with 0% FPR (95% CI, 0%-14%). Status myoclonus at 24 hours after cardiac arrest has a more precise 0% FPR (95% CI, 0%-3%).^{277,278} Similar patterns of findings are true among patients treated with therapeutic hypothermia, though longer periods of observation may be required to clear potential confounding factors by sedation.

Physiologic response to targeted temperature management provides another avenue for insight into the potential for neurologic recovery. The presence of shivering,²⁹⁰ the amount of patient heat generation (derived from the inverse average water temperature of cooling devices),²⁹¹ and the presence of bradycardia (<60 beats/minute)²⁹² during the induction and maintenance of temperature management are each associated with favorable neurologic outcome.

Imaging Studies

Imaging of the brain is important to exclude injury incurred at the time of collapse and to exclude intracranial causes of collapse. A noncontrast cranial computed tomography (CT) scan to exclude hemorrhage is prudent in comatose patients after cardiac arrest and prior to anticoagulation or fibrinolytic therapy.^{293,294} In general, noncontrast CT scan is insufficiently sensitive to determine prognosis after cardiac arrest unless severe changes are present, such as generalized edema that is often associated with loss of brainstem reflexes and may progress to herniation and brain death (Fig. 50-7). The amount of brain edema can be quantified with a ratio of attenuation (Hounsfield units) in select regions of gray matter and white matter. This "gray-to-white ratio" is directly associated with survival and functional outcome.^{295,296} Whether treatment of cerebral edema is worthwhile or futile has not yet been studied.

Magnetic resonance imaging (MRI) can visualize subtler changes in brain after cardiac arrest. For example, increased cortical signals on diffusion-weighted images (DWI) or fluid-attenuated inversion recovery (FLAIR) are associated with poor neurologic outcome.²⁹⁷ For patients who remain comatose for several days and in whom clinical or electrophysiologic testing is indeterminate, MRI can provide additional information about the extent of brain injury. Expectations and enthusiasm for long-term support may be reduced if extensive cortical lesions are present, whereas persistence may be justified if anatomic extent of injury appears limited. An important caveat with interpretation of all brain imaging after global ischemia is the differing clinical impact of lesions in different brain regions. The anatomic complexity of the brain precludes any simple quantitative relationship between the number or size of lesions and outcome. Isolated DWI abnormalities in single anatomic locations are not specific for poor neurologic outcome.²⁹⁸ Furthermore, the existing literature about MRI is limited by indication bias: only a select subgroup of patients who are not improving clinically have this test, potentially inflating the prognostic significance of any findings. Long-term cognitive deficits are associated with global brain volume loss after cardiac arrest.²⁹⁹ MRI should be used as an adjunct for assessing postcardiac arrest brain damage in centers with neurologic or neuroradiologic expertise for interpreting these tests.

Neurophysiology

Electroencephalogram (EEG) patterns after resuscitation change over time.^{300,301} The greatest utility of an EEG is to diagnose seizures and exclude nonconvulsive seizures as an etiology of unresponsiveness. Seizures are diagnosed clinically in 5% to 20% of comatose patients after cardiac arrest,^{184,301} and the true incidence of nonconvulsive electrographic seizures may be higher. Termination of seizures, if possible, is essential to allow untainted assessment of the neurologic examination (Fig. 50-8). Certain malignant EEG patterns have a strong association with poor outcome. Specifically, generalized suppression

BOX 50-1 Post-Cardiac Arrest Category

The category of a patient can be assessed quickly on arrival to better stratify the initial probability of survival and risk of different complications. Precise research definitions of the categories use scoring systems assessed within 6 hours of return of pulses,²⁸⁷ but clinical examination can usually sort patients into categories. Neurologic examination cannot be assessed if drugs or paralytics are confounding.

CATEGORY 1—AWAKE (FOLLOWS COMMANDS)

80% chance of survival; 60% chance of good functional recovery
<5% chance of multiple organ failure

CATEGORY 2—COMA WITH PRESERVED BRAINSTEM REFLEXES*

60% chance of survival; 40% chance of good functional recovery
20% chance of multiple organ failure

CATEGORY 3—COMA WITH PRESERVED BRAINSTEM REFLEXES AND SEVERE CARDIOPULMONARY FAILURE**

40% chance of survival; 20% chance of good functional recovery
40% chance of multiple organ failure

CATEGORY 4—COMA WITH LOSS OF BRAINSTEM REFLEXES

10% chance of survival; 7% chance of good functional recovery
35% chance of multiple organ failure

*Coma with preserved brainstem reflexes = FOUR score Motor + Brainstem scale ≥ 4 ; typically present pupillary light reflex, corneal reflex, and some movement of extremities (at least posturing)

**Severe cardiopulmonary failure = SOFA score cardiac + respiratory subscales ≥ 4 ; typically more than one pressor drug, norepinephrine or equivalent at rates $>0.1 \mu\text{g/kg/min}$ and/or ventilator settings with $\text{PaO}_2/\text{FiO}_2$ ratio <100 .

FIGURE 50-7 ■ Imaging of the brain after cardiac arrest. **A**, Severe cerebral ischemia appears as sulcal effacement, with loss of contrast between gray matter and white matter. Congestion of blood in meninges (pseudosubarachnoid hemorrhage [arrow]) sometimes is evident. This pattern on early computed tomography (CT) scan often progresses to herniation and brain death. **B**, Less severe early changes show edema (hypodensity) restricted to basal ganglia (arrow), with sparing of cortex. **C**, Increased magnetic resonance imaging (MRI) signal from extensive areas of cortex on diffusion-weighted images (DWI) of this patient correspond to devastating brain injury with persistent coma. This patient showed no improvement in coma. **D**, DWI for same patient in **B** illustrates high-intensity signal from damaged subcortical areas. In this case, cortex and other structures are normal. After 5 days of coma, this patient awoke, completed rehabilitation, and recovered completely.

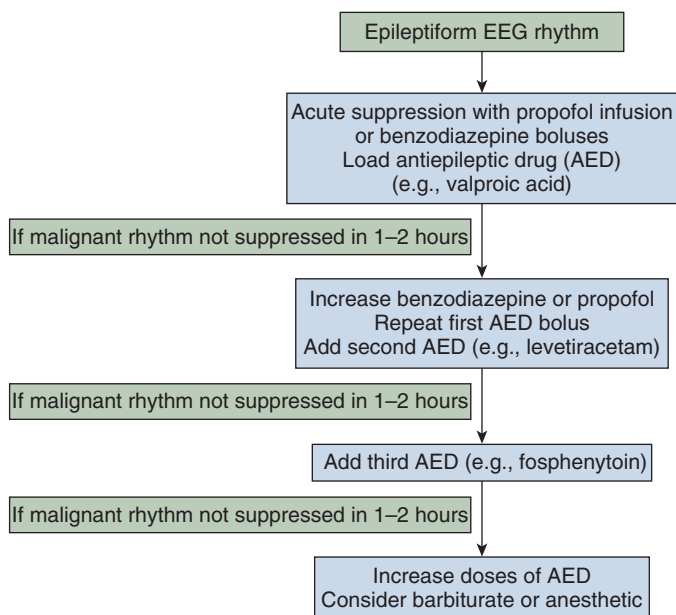

FIGURE 50-8 ■ EEG examination and AED management following resuscitation.

(<20 μ V), burst-suppression pattern associated with generalized epileptic activity, or diffuse periodic complexes on a flat background during the first week after resuscitation are associated with poor neurologic outcome.²⁷⁹ The presence of malignant EEG patterns provides information that is additive with clinical evaluation.³⁰² Thus EEG cannot be used by itself to determine prognosis, but the information provided by EEG can exclude confounders (seizures) and can be integrated into the total clinical picture used to assess prognosis.

Electrophysiologic response to stimuli can also be used to assess whether cortical regions are intact. Recovery of longer latency event-related potentials are associated with awakening.³⁰³⁻³⁰⁵ Conversely, absence of short latency (N20) cortical response to somatosensory evoked potentials (SSEPs) is very specific for poor neurologic outcome

(FPR 0%; 95% CI, 0%-2%) among patients treated with therapeutic hypothermia.^{276,278,279} Like EEG, SSEP responses vary with the elapsed time since resuscitation.³⁰⁰ Recent data suggest that the use of therapeutic hypothermia may increase the time-dependent changes in SSEP. One case series reported two patients treated with hypothermia who had absent N20 responses at 3 days after cardiac arrest but recovered cognition.²⁸³ Therefore, it may be reasonable to repeat SSEPs that show absent N20s several days apart in order to avoid false-negative tests.

Blood Markers

Several peptides appear in the blood after brain injury, including neuron-specific enolase (NSE) and the glia-derived protein, S-100B. After cardiac arrest, NSE reaches a maximum level in serum at 72 hours. High NSE levels at 48 to 72 hours or NSE levels that continue to rise over the first 72 hours after resuscitation are associated with poor outcome.³⁰⁵⁻³⁰⁷ In contrast to NSE, peak levels of S-100B in serum occur during the first 24 hours after resuscitation, and higher S-100B levels are associated with poor neurologic outcome.^{306,308} Hypothermia treatment appears to alter serum NSE levels.³⁰⁹ Use of NSE or S-100B to determine prognosis is limited by the absence of a clear cutoff value that is unsurvivable and the lack of universal standard for laboratory assays. NSE can also be released by injury to nonbrain organs.³¹⁰ These neuronal markers might be considered a tool for following brain injury, analogous to troponin levels for following myocardial injury, but lack the specificity or clarity required to guide therapeutic decisions.

In summary, the determination of neurologic prognosis after cardiac arrest varies from patient to patient. Changes in clinical examination are the cornerstone of prognostication. While the patient is recovering, hypothermia and supportive care may increase the likelihood of recovery. However, electrophysiologic and imaging techniques can add additional useful information to help guide clinicians and families. The approximate timing for each of these studies is depicted in Figure 50-9. New prognostication guidelines from the European Resuscitation Council and European Society of Intensive Care Medicine³¹¹ emphasize the bilateral absence of pupillary and corneal reflexes or N20 wave of SSEPs as the most robust predictors of poor outcome irrespective of temperature management. Early myoclonus, elevated

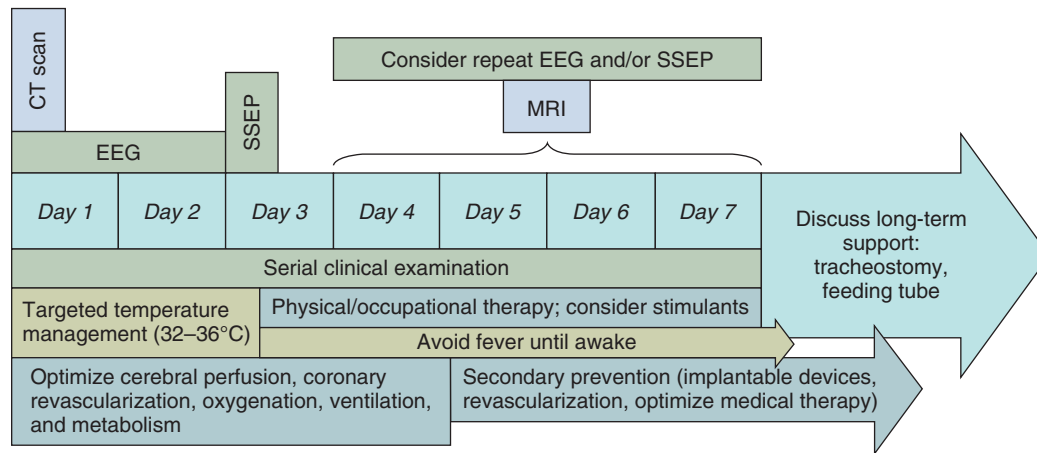

FIGURE 50-9 ■ Rational approach to neurologic treatment, monitoring, and testing after cardiac arrest. For patients remaining in coma, hypothermia treatment followed by therapy and stimulation may improve recovery. Early electroencephalogram (EEG) monitoring is recommended not for prognosis but to allow detection and treatment of seizures. Absence of cortical response on somatosensory evoked potential (SSEP) or malignant EEG patterns after hypothermia treatment may help identify subsets of patients unlikely to ever show improvement. When those tests are indeterminate, and there is no sign of clinical improvement, magnetic resonance imaging (MRI) of the brain may help quantify extent and location of injury, which in turn assists in decisions about continuing long-term support. Most tests are not required when patients exhibit clear clinical improvement. Conversely, patients who progress to brain death should undergo brain death testing once toxicologic confounds, metabolic abnormalities, and shock have been corrected.

values of NSE at 48 to 72 hours from cardiac arrest, unreactive malignant EEG patterns after rewarming, and diffuse signs of anoxic injury on CT or MRI are useful but less robust predictors. Prolonged observation should be considered when the results of initial assessments are inconclusive.

REHABILITATION

The role of rehabilitation or other therapy in recovery from neurologic impairment after cardiac arrest is relatively unstudied. It is clear that both patients and their caregivers have complex needs if neurologic injury is severe.³¹² Older data suggests that long-term improvement is less common when neurologic devastation follows a medical cause like cardiac arrest than when it results from traumatic brain injury.²⁷³ More recent work suggests that rehabilitation can produce similar improvements after global brain ischemia.^{313,314} Nevertheless, early consideration of rehabilitative services including physical therapy and occupational therapy may help promote recovery, just as in acute stroke.³¹⁵ Physical stimulation and maintenance of muscle tone could conceivably promote awakening. When arousal or level of consciousness is impaired after traumatic brain injury, stimulants such as methylphenidate or amantadine have been employed with reduction in total ICU stay or improved final status.^{316,317} While these data are few and indirect, addition of stimulants for postcardiac arrest patients who linger in intermediate coma might be considered, if medically tolerated.³¹⁸

WITHDRAWAL OF LIFE-SUSTAINING TREATMENT

For adults who are neurologically devastated after cardiac arrest in North America, it is more common to die in a hospital than to receive long-term care. An estimated 44% of patients who are initially resuscitated from cardiac arrest in a hospital have withdrawal of care later in their hospitalization.¹⁴ For patients resuscitated from out-of-hospital

cardiac arrest, 61% die after withdrawal of life-sustaining treatments because of predicted neurologic prognosis.²³ Because these decisions are often based on the neurologic prognosis of the patient, withdrawal of life-sustaining treatment limits the number of neurologically impaired individuals who are discharged from the hospital. Consequently, quality of life for those patients who do leave the hospital is generally high.^{21,319,320} Popular reports of awakening after long coma may cause inappropriate optimism for families of patients or surrogate decision makers. Partial awakening of patients into a persistent vegetative state or minimally conscious state can further confuse their expectations. Decision makers should receive information about these syndromes, realistic expectations of recovery, and any specific considerations for the individual patient. Religious, cultural, and personal beliefs will contribute to decisions, and appropriate social service and pastoral support should be provided. Finally, for patients who survive cardiac arrest but who later progress to death or brain death, it is reasonable to evaluate their candidacy to become organ donors: outcomes for transplanted organs from this population are comparable to all other donors.³²¹

SUMMARY

Improvement in outcome after cardiac arrest will require attention both to the reversal of cardiopulmonary arrest and to restoration of consciousness. Isolated attention to only the heart or only the brain is unlikely to improve outcomes for many patients. Appropriate prioritization of the various tools for cardiac resuscitation, along with emphasis on the basic mechanics of artificial circulation, may increase the number of individuals reaching the ICU. Induction of mild hypothermia, management of blood pressure and respiration, along with proper treatment of the root cause of the cardiac arrest may increase the number of initially comatose patients who awaken. Constant reassessment of the likelihood of meaningful recovery, based on clinical examination and ancillary testing, can guarantee that continued care and interventions are appropriate.

KEY POINTS

1. Improvement in outcome after cardiac arrest requires attention both to immediate reversal of cardiopulmonary arrest and promoting recovery of brain function through subsequent intensive care unit (ICU) interventions. Isolated attention to only the heart or only the brain is unlikely to improve outcomes for many patients (see Fig. 50-8).
2. Increased emphasis on the basic mechanics of artificial circulation, specifically uninterrupted vigorous chest compressions, may increase the number of individuals reaching the ICU.
3. It is necessary to prioritize the various adjunct tools for cardiac resuscitation. For example, time devoted to tracheal intubation may delay drug therapy and interrupt chest compressions without altering overall hemodynamics.
4. The cornerstone of drug therapy during resuscitation attempts is the selective administration of vasoactive drugs that will increase coronary perfusion pressure developed by chest compressions. Rote, repeated administration is unlikely to result in favorable neurologic outcome.
5. Induction of targeted temperature management; optimal management of blood pressure, oxygenation, and ventilation; and proper treatment of the root cause of the cardiac arrest may increase the number of initially comatose patients who awaken.
6. Neurologic prognosis is determined using serial clinical examinations supplemented by neurophysiologic or imaging tests. Clinical examination continues to change for many days after cardiac arrest, and even longer periods of observation may be required for patients treated with hypothermia. Constant reassessment of the likelihood of meaningful recovery can guarantee that continued care and interventions are appropriate.

ANNOTATED REFERENCES

This study noted the high incidence of unintentional hyperventilation when manual bagging was used during actual resuscitations. This common practice has adverse hemodynamic effects that can reduce survival, and training is proposed to prevent hyperventilation.
- Bobrow BJ, Ewy GA, Clark L, Chikani V, Berg RA, Sanders AB, et al. Passive oxygen insufflation is superior to bag-valve-mask ventilation for witnessed ventricular fibrillation out-of-hospital cardiac arrest. *Ann Emerg Med* 2009;54:656–662.
This paper discusses not using positive pressure ventilation at all during the initial resuscitation and reports higher neurologically intact survival when passive insufflation of oxygen was chosen over bag-valve-mask ventilation.
- Callaway CW, Schmicker RH, Brown SP, Albrich JM, Andrusiek DL, Aufderheide TP, et al. Early coronary angiography and induced hypothermia are associated with survival and functional recovery after out-of-hospital cardiac arrest. *Resuscitation* 2014;85:657–663.
This secondary analysis of a large clinical trial demonstrated that odds of survival and good functional recovery are increased when patients receive emergent coronary interventions and temperature management during hospitalization.
- Christenson J, Andrusiek D, Everson-Stewart S, Kudenchuk P, Hostler D, Powell J, et al. Resuscitation Outcomes Consortium Investigators. Chest compression fraction determines survival in patients with out-of-hospital ventricular fibrillation. *Circulation* 2009;120:1241–1247.
This study monitored the performance of chest compressions in out-of-hospital VF. There is a strong association between survival and the proportion of time when chest compressions are performed (chest-compression fraction).
- Hagihara A, Hasegawa M, Abe T, Nagata T, Wakata Y, Miyazaki S. Prehospital epinephrine use and survival among patients with out-of-hospital cardiac arrest. *JAMA* 2012;307:1161–1168.
This large observational data set examined the introduction of prehospital epinephrine use in Japan. The use of epinephrine increased the number of patients with return of pulses and arrival to a hospital but decreased the absolute number of long-term survivors.
- Nielsen N, Wetterslev J, Cronberg T, Erlinge D, Gasche Y, Hassager C, et al. Targeted temperature management at 33°C versus 36°C after cardiac arrest. *N Engl J Med* 2013;369:2197–2206.
This trial in patients with out-of-hospital cardiac arrest detected no difference in short- or long-term outcomes between two temperature management regimens: 33°C versus 36°C for 24 hours. The outcomes for both groups were similar to the intervention groups in prior trials and much better than the outcomes in prior control groups that had no temperature management, supporting the use of active temperature management, even at a higher temperature of 36°C.
- Olasveengen TM, Sunde K, Brunborg C, Thowsen J, Steen PA, Wik L. Intravenous drug administration during out-of-hospital cardiac arrest: a randomized trial. *JAMA* 2009;302:2222–2229.
This study compared resuscitation of patients with out-of-hospital cardiac arrest with and without IV drugs in a mature and well-monitored system, with attention to postcardiac arrest care. Although IV drugs improved the rate of restoration of circulation, there was no difference in long-term outcome, challenging the current role of IV drugs during resuscitation.
